1 INTRODUCTION

The COSY¹ experiment (Figure 1) is probably the single most important two-dimensional NMR experiment. The experiment provides a homonuclear chemical shift correlation: if two spins are connected by a scalar coupling, then the COSY spectrum will show a pair of symmetrical cross peaks between the diagonal peaks of two spins (see *COSY Two-Dimensional Experiments*). Although the SECSY experiment was often used for homonuclear correlation,^{2,3} COSY is the one that has survived. It is the simplest pulse sequence, requires no prior knowledge of the spin parameters, is the easiest to analyze theoretically, provides some of the most useful structural information, and is probably the most widely used 2D experiment. For these reasons, there are several variations on the basic experiment. To begin with, a 2D experiment is not just a pulse sequence but also the associated phase cycling sequence, so that must be considered. COSY has also been the subject of many theoretical investigations. The information that it provides is often simply qualitative (on what is coupled to what), but it is important to understand the quantitative basis of COSY as well.

A quantitative analysis of COSY is needed to understand the conditions under which the experiment will work. Many spin systems have a variety of coupling constants ranging from large geminal couplings of 15 Hz or more, through typical vicinal couplings of a few Hz, down to long-range couplings of a fraction of a Hz. Under what circumstances will these couplings show up as cross peaks in a COSY? In a

Figure 1 COSY pulse sequence. The initial $\pi/2$ pulse excites the spin system which evolves during the regularly-incremented delay t_1 . The second pulse is called the mixing pulse and may have any flip angle, α . For many applications, $\alpha = \pi/2$ or $\alpha = \pi/4$

complex system, a multiplet will consist of several splittings corresponding to couplings to several different spins. What are the intensity ratios within a multiplet? Do any new frequencies appear in f_1 ? In a COSY cross peak connecting two spins, how does the active coupling (the one between the two spins in question) appear relative to the passive couplings to the other spins in the system? What happens if the flip angles or the phase cycling sequence is changed? What happens if the spin system does not reach equilibrium between pulse sequences? What is the role of phase cycling and quadrature detection? These are just some of the questions that arise from a detailed examination of the COSY experiment.

Understanding the COSY experiment is relatively easy since it is such a simple experiment. The manipulations are straightforward matrix operations and no more difficult than simple spectral analysis. COSY can also serve as a prototype for all multidimensional experiments, since it illustrates many of the principles seen in more complex techniques. In this article, we discuss a simple COSY experiment on a two-spin system in detail. This will cover many of the points raised in the previous paragraphs and serve as a basis for a discussion of more complex systems.

2 COSY ON A TWO-SPIN SYSTEM

The simplest system has two spins $\frac{1}{2}$, labeled A and B, with Larmor frequencies of ν_A and ν_B . These spins are scalar-coupled with a coupling constant of J , so the spectrum consists of two doublets. Figure 2 shows the energy levels and the allowed transitions. We assume the coupling is weak, so that all four lines in the spectrum have the same intensity. These four lines in the spectrum correspond to density matrix elements which oscillate at these four frequencies. The four lines will all mix with each other in a COSY, so there will be 16 lines in the two-dimensional spectrum. We can study the frequencies, intensities, and phases of these 16 lines by following the modulation of the basic spectrum in the 2D experiment.

2.1 Basic Theory

For any line in a spectrum at frequency ν (in the rotating frame of reference), there are two associated oscillating density matrix elements. These can be thought of as the x and the

Figure 2 The energy levels of a two spin- $\frac{1}{2}$ system and the allowed single quantum transitions. The two spins, labeled A and B, have Larmor frequencies ν_A and ν_B , and are scalar coupling with a coupling constant of J

y magnetization, or as two counter-rotating magnetizations rotating at the appropriate frequency. We choose the latter picture, and denote the two density matrix elements as $|+\nu\rangle$ and $|-\nu\rangle$. Any coherence associated with the density matrix element $|+\nu\rangle$ will evolve during a delay time, t , as $e^{+i\nu t}$. The terms positive and negative, strictly speaking, refer to the coherence level, a quantum number associated with each coherence. Of course, the frequencies may themselves be either positive or negative with respect to the carrier frequency, and coupling constants may have either sign. This provides the mathematical description of the rotating magnetization.

2.2 Excitation and Evolution

The COSY experiment consists of an excitation pulse, an evolution time t_1 , a mixing pulse, and then detection. We will assume that the spin system is in equilibrium at the start of the sequence. The $\pi/2$ excitation pulse in Figure 1 creates coherence corresponding to the four lines in the spectrum, which we will allow to have unit intensity, for simplicity. There will be four positively-rotating elements and four negative ones. These will evolve during the evolution time, so that at the end of t_1 the positively-rotating density matrix elements are given by equation (1).

$$\left. \begin{aligned} |v_A + J/2\rangle &= e^{+i(v_A + J/2)t_1} \\ |v_A - J/2\rangle &= e^{+i(v_A - J/2)t_1} \\ |v_B + J/2\rangle &= e^{+i(v_B + J/2)t_1} \\ |v_B - J/2\rangle &= e^{+i(v_B - J/2)t_1} \end{aligned} \right\} \quad (1)$$

Similarly, the elements at negative frequency are given by equation (2).

$$\left. \begin{aligned} |-v_A - J/2\rangle &= e^{-i(v_A + J/2)t_1} \\ |-v_A + J/2\rangle &= e^{-i(v_A - J/2)t_1} \\ |-v_B - J/2\rangle &= e^{-i(v_B + J/2)t_1} \\ |-v_B + J/2\rangle &= e^{-i(v_B - J/2)t_1} \end{aligned} \right\} \quad (2)$$

The mixing pulse in the COSY experiment ends the evolution. The effect of this pulse is the key to the experiment, determining what frequencies will appear in f_1 and with which intensities and phases. In general, the calculation of the effect of a pulse with general flip angle and phase on a general spin system is quite complex and beyond the scope of this article. The simple evolution during a delay, as above, is relatively easy to picture, but the effect of a pulse is the subject of several theoretical descriptions for pulse NMR.^{4,5}

2.3 Frequencies in a COSY Spectrum

The mixing pulse should not introduce any new frequencies into the spectrum, so that any frequency that appears in f_1 in a COSY spectrum should also be there in the simple 1D spectrum. The 1D spectrum may be quite complex (see *Analysis of High-Resolution Solution State Spectra*), but regardless of how complicated the spectrum is no new frequencies will be present in f_1 . The principal assumption behind this sweeping statement is that the spin system should be in equilibrium before the pulse sequence starts.

This assumption is seldom true in routine practice of COSY. Artifacts⁶ are quite common in COSY spectra, but these artifacts are usually simple multiples of the genuine f_1 frequencies. A more detailed discussion of these artifacts and strategies to suppress them is given later.

The reason that no new frequencies are introduced is that only single quantum transitions are excited and detected. A nonselective pulse acting on any spin system in equilibrium will produce only single quantum transitions: the normal equilibrium spectrum. If we ignore relaxation effects, the single quantum transitions will evolve only amongst themselves during the delay. Even though the mixing pulse may create all orders of multiple quantum coherence, only single quantum coherence can be detected directly. In fact, quadrature detection implies that only one of the two senses of precession will be detected, so that only one of the two sets, equation (1) or equation (2), will be observed. Hence, a two-pulse experiment like COSY acting on a spin system in equilibrium will only involve single quantum transitions.

The fact that frequencies in f_2 become frequencies in f_1 means that there is a symmetry to the COSY spectrum.⁷ Cross peaks should always occur as symmetrically placed pairs about the main diagonal. This is a very powerful result. It can help us in sorting out genuine cross peaks from artifacts, since artifacts are very seldom symmetrical.

2.4 The Mixing Pulse

In the COSY experiment, where we are dealing only with single quantum coherence, the effect of the pulse is relatively simple. For a weakly coupled spin system subjected to pulses whose flip angles and phases are multiples of $\pi/2$, product operator methods are the most popular approach. In this article, we will take a more general approach in order to see what happens when we go beyond the simple systems. The possible frequencies of lines in f_1 are defined by the one-dimensional spectrum for all types of spin systems and flip angles/phases of the mixing pulse. We must calculate the intensities and phases of the lines under these circumstances.

The effect of a pulse is best handled by using the angular momentum properties of the spin system. A pulse is equivalent to a rotation of the frame of reference (see *Radiofrequency Pulses: Response of Nuclear Spins*) and angular momentum functions, or spherical tensors, provide a natural basis for describing what happens during a rotation. For any spin system we can convert to a spherical tensor basis, and then the effect of a pulse is simply given by a Wigner matrix element, independent of the details of the spin system.

Among the single quantum transitions, the pulse can take a positive frequency and mix it with the other positive frequencies; it can take a positive frequency, reverse its sense of precession and mix it with the negative frequencies; or it can put a rotating magnetization back up on the z axis. We will ignore the magnetization put back along z and then treat each of the two other cases separately.

The matrix that takes the positive frequencies into the negative frequencies is given by equation (3). Equation (4) gives the matrix which takes the positive frequencies into themselves.

$$\begin{bmatrix} \frac{1}{2} \sin^2 \frac{\alpha}{2} (1 + \cos \alpha) & \frac{1}{2} \sin^2 \frac{\alpha}{2} (1 - \cos \alpha) & \frac{\sin^2 \alpha}{4} & \frac{-\sin^2 \alpha}{4} \\ \frac{1}{2} \sin^2 \frac{\alpha}{2} (1 - \cos \alpha) & \frac{1}{2} \sin^2 \frac{\alpha}{2} (1 + \cos \alpha) & \frac{-\sin^2 \alpha}{4} & \frac{\sin^2 \alpha}{4} \\ \frac{\sin^2 \alpha}{4} & \frac{-\sin^2 \alpha}{4} & \frac{1}{2} \sin^2 \frac{\alpha}{2} (1 + \cos \alpha) & \frac{1}{2} \sin^2 \frac{\alpha}{2} (1 - \cos \alpha) \\ \frac{-\sin^2 \alpha}{4} & \frac{\sin^2 \alpha}{4} & \frac{1}{2} \sin^2 \frac{\alpha}{2} (1 - \cos \alpha) & \frac{1}{2} \sin^2 \frac{\alpha}{2} (1 + \cos \alpha) \end{bmatrix} \quad (3)$$

$$\begin{bmatrix} \frac{1}{2} \cos^2 \frac{\alpha}{2} (1 + \cos \alpha) & \frac{1}{2} \cos^2 \frac{\alpha}{2} (1 - \cos \alpha) & \frac{-\sin^2 \alpha}{4} & \frac{\sin^2 \alpha}{4} \\ \frac{1}{2} \cos^2 \frac{\alpha}{2} (1 - \cos \alpha) & \frac{1}{2} \cos^2 \frac{\alpha}{2} (1 + \cos \alpha) & \frac{\sin^2 \alpha}{4} & \frac{-\sin^2 \alpha}{4} \\ \frac{-\sin^2 \alpha}{4} & \frac{\sin^2 \alpha}{4} & \frac{1}{2} \cos^2 \frac{\alpha}{2} (1 + \cos \alpha) & \frac{1}{2} \cos^2 \frac{\alpha}{2} (1 - \cos \alpha) \\ \frac{\sin^2 \alpha}{4} & \frac{-\sin^2 \alpha}{4} & \frac{1}{2} \cos^2 \frac{\alpha}{2} (1 - \cos \alpha) & \frac{1}{2} \cos^2 \frac{\alpha}{2} (1 + \cos \alpha) \end{bmatrix} \quad (4)$$

These equations are valid for any flip angle, α , of the mixing pulse applied to a weakly coupled spin system. For $\alpha = \pi$, note that the matrix in equation (4) vanishes completely and the only elements in equation (3) that survive are the ones that connect the two lines in each doublet together: elements (1,2), (2,1), (3,4), and (4,3). This is the mixing in the multiplets that gives rise to J -modulation in spin echoes (see *Two-Dimensional J-Resolved Spectroscopy*).

The simple COSY experiment involves a $\pi/2$ mixing pulse, so we must include the effects of both matrices. Since we detect only one sense of precession, say the positive one, we need only calculate the coherences that contribute to that set. Therefore, to describe what the mixing pulse does, we multiply the coherences in equation (2) by the matrix in equation (3) — these are the coherences with a negative coherence level going into the positives. The result of this is given in equation (5).

$$\begin{aligned} |v_A + J/2\rangle &= \frac{1}{4} [e^{-i(v_A + J/2)t_1} + e^{-i(v_A - J/2)t_1} + e^{-i(v_B + J/2)t_1} - e^{-i(v_B - J/2)t_1}] \\ |v_A - J/2\rangle &= \frac{1}{4} [e^{-i(v_A + J/2)t_1} + e^{-i(v_A - J/2)t_1} - e^{-i(v_B + J/2)t_1} + e^{-i(v_B - J/2)t_1}] \\ |v_B + J/2\rangle &= \frac{1}{4} [e^{-i(v_A + J/2)t_1} - e^{-i(v_A - J/2)t_1} + e^{-i(v_B + J/2)t_1} + e^{-i(v_B - J/2)t_1}] \\ |v_B - J/2\rangle &= \frac{1}{4} [-e^{-i(v_A + J/2)t_1} + e^{-i(v_A - J/2)t_1} - e^{-i(v_B + J/2)t_1} + e^{-i(v_B - J/2)t_1}] \end{aligned} \quad (5)$$

Added to this is the result of applying the matrix in equation (4) to the coherences in equation (1). The contribution of the positive coherences is given by equation (6).

$$\begin{aligned} |v_A + J/2\rangle &= \frac{1}{4} [e^{+i(v_A + J/2)t_1} + e^{+i(v_A - J/2)t_1} - e^{+i(v_B + J/2)t_1} + e^{+i(v_B - J/2)t_1}] \\ |v_A - J/2\rangle &= \frac{1}{4} [e^{+i(v_A + J/2)t_1} + e^{+i(v_A - J/2)t_1} + e^{+i(v_B + J/2)t_1} - e^{+i(v_B - J/2)t_1}] \\ |v_B + J/2\rangle &= \frac{1}{4} [-e^{+i(v_A + J/2)t_1} + e^{+i(v_A - J/2)t_1} + e^{+i(v_B + J/2)t_1} + e^{+i(v_B - J/2)t_1}] \\ |v_B - J/2\rangle &= \frac{1}{4} [e^{+i(v_A + J/2)t_1} - e^{+i(v_A - J/2)t_1} + e^{+i(v_B + J/2)t_1} + e^{+i(v_B - J/2)t_1}] \end{aligned} \quad (6)$$

The final result is the sum of equations (5) and (6), to give the expressions in equation (7).

$$\begin{aligned} |v_A + J/2\rangle &= \frac{1}{4} [\cos(v_A + J/2)t_1 + \cos(v_A - J/2)t_1 - \sin(v_B + J/2)t_1 + \sin(v_B - J/2)t_1] \\ |v_A - J/2\rangle &= \frac{1}{4} [\cos(v_A + J/2)t_1 + \cos(v_A - J/2)t_1 + \sin(v_B + J/2)t_1 - \sin(v_B - J/2)t_1] \\ |v_B + J/2\rangle &= \frac{1}{4} [-\sin(v_A + J/2)t_1 + \sin(v_A - J/2)t_1 + \cos(v_B + J/2)t_1 + \cos(v_B - J/2)t_1] \\ |v_B - J/2\rangle &= \frac{1}{4} [\sin(v_A + J/2)t_1 - \sin(v_A - J/2)t_1 + \cos(v_B + J/2)t_1 + \cos(v_B - J/2)t_1] \end{aligned} \quad (7)$$

This is the modulation of the lines resulting from the simple pulse sequence in Figure 1. The modulation is a cosine modulation, with the diagonal peaks (the peaks due to mixing within a multiplet) $\pi/2$ out of phase with the cross peaks, and the two cross peaks of opposite sign. Since this is a cosine modulation, a real Fourier transform (as distinct from a complex one) will extract the data. Depending on the phase correction used, the diagonal peaks will be dispersion in both dimensions and the cross peaks will be absorption in both f_1 and f_2 . This is the basic COSY experiment (note that no phase cycling was done), but there are problems with it and many variations have been developed.

2.5 Different Types of COSY

The different types of COSY experiment generally do not change the basic pulse sequence in Figure 1, but rather vary the associated phase cycling scheme and the way that the data are transformed. One of the problems is that the cosine modulation in equation (7) cannot distinguish between positive and negative frequencies, so quadrature detection in f_1 is not possible. In itself this is not too much of a problem, since quadrature detection in f_1 does not give any signal to noise ratio advantage.⁸ However, the lack of quadrature detection in f_1 in a homonuclear experiment prevents its use in f_2 where there is an advantage to its use.

Historically, the first solution to the problem was to use a complex FT, that is to use $e^{i\omega t}$ in the transform rather than $\cos(\omega t)$. When applied to the data in equation (7), this gives peaks at both positive and negative frequencies, since $\cos(\omega t) = 1/2(e^{i\omega t} + e^{-i\omega t})$. These peaks were called P-type and N-type peaks.² One or other of these can be removed by phase cycling — repeating the same pulse sequence, but with different phases in the pulses^{9,10} (see *Phase Cycling*). This removes (usually) the positive-to-positive transfer given by equation (6), so that the data have a complex modulation

Figure 3 The so-called 'phase twist' lineshape often encountered in COSY spectra. In the center of the lineshape is pure absorption, but in the wings in each dimension it becomes more dispersion-like

given by equation (5). The disadvantage of this method is that the lineshapes no longer have a pure phase, but rather a so-called phase twist in which the phase in one dimension changes as one moves across the other dimension. Figure 3 shows the phase twist lineshape. This phase problem can be circumvented by the use of pseudoecho, or sine-bell type apodization functions, and a magnitude calculation rather than a phase correction after the 2D FT. This form of the COSY experiment is very popular and very simple to set up and process.

Figures 4, 5, 6, 7, and 8 show typical results from such an experiment on the molecule serine. Serine is a convenient sample for experimenting with 2D NMR since the chemical shifts of the protons can be easily manipulated by changing the pH of the solution.

Two other solutions to the quadrature detection problem keep the pure phase lineshapes. One is effectively to move $f_1 = 0$ through the use of the time proportional phase increment (TPPI) and still use a real FT.¹¹ The other method is to collect a parallel data set that is phase-shifted, so that there is true complex data in both dimensions.¹² Both methods are widely used and except for some minor details in the baseline the two are essentially equivalent.¹³

The final problem is to make all of the lines, both cross peaks and diagonal peaks, the same phase. If we use a double quantum filter in the mixing pulse,^{14,15} this achieves the goal of a homonuclear correlation with pure absorption lines.

For the analysis of the fine structure within a multiplet, the COSY experiment with phase sensitive transforms and double quantum filtering is the method of choice. For quick, qualitative experiments to determine a rough connectivity network, the magnitude calculation COSY is quicker to set up and process (in fact it can easily be set up automatically by the spectrometer). Depending on what sort of information is required, one of these two experiments is used in most cases.

2.6 Intensities of Cross Peaks and Digitization Effects

The fact that the two elements in the cross peak in equations (5) and (6), are of opposite sign is a general one: the cross peaks always have zero net intensity if the acquisition begins

Figure 4 Magnitude calculation COSY on serine, $\text{NH}_2\text{CH}(\text{CH}_2\text{OH})(\text{COOH})$, in D_2O at pH 10 at a spectrometer frequency of 300 MHz. The mixing pulse had a flip angle of $\pi/2$. The raw data consisted of 256 FIDs of 1 k data points, which were Fourier-transformed using an unshifted sine-bell squared apodization in both dimensions. The spectral width in both dimensions was 338 Hz, giving a digital resolution of 0.66 Hz per point. The α proton in serine is at low frequency and the two β protons, β and β' , are 0.339 and 0.410 ppm to high frequency at this pH. The measured coupling constants are $J_{\alpha\beta} = 5.9$ Hz, $J_{\alpha\beta'} = 4.3$ Hz, and $J_{\beta\beta'} = -11.2$ Hz

immediately after the mixing pulse. For a weakly coupled AX system as above, the ratio of the peaks is 1: - 1. For more complex multiplets, the relative intensities can be built up from the AX case as for 1D spectra. For equivalent spins, Pascal's triangle can be used so that for the cross peak in an AX_2 system the ratios of the peaks are 1:0: - 1 and the peaks in an AX_3 system are in the proportion of 1:1: - 1: - 1. These ratios will be evident in a phase sensitive COSY, but a magnitude calculation COSY will mask the signs of the peaks.

In a more complex spin system, the distinction between active and passive couplings becomes important. Within a given set of cross peaks, representing the correlation between spin A and spin X, the J_{AX} is the active coupling. This coupling will appear as an antiphase arrangement, as above, but all the other couplings will appear as normal. The splitting due to coupling from A to another spin, M, will appear in phase within the AX cross-peak group. Of course, in the cross-peak group joining A and M, then J_{AM} will be the active coupling.

As the coupling approaches zero the cross peak should vanish, so the net cross-peak intensity must be zero. However, adding a delay after the mixing pulse before the start of the acquisition will enhance cross peaks due to long-range coupling. This delay should be some fraction of the coupling,

Figure 5 Plot of a row from the data matrix in Figure 4 (trace b) and a simulation of the same data (trace a). The row corresponds to the row of peaks at the bottom of the spectrum (highest frequency in f_1). The spectrum was simulated using the SIMPLTN program which provides an exact density matrix calculation

Figure 6 Magnitude calculation COSY on the same serine sample as in Figure 4, also with a mixing pulse of $\pi/2$ but at 500 MHz. The spectral width and the number of experiments is the same as in Figure 4

so that the peaks that are exactly out of phase after the mixing pulse have some time to approach being in phase. Similarly, a delay before the mixing pulse will allow multiplets time to get out of phase and enhance polarization transfer. If these delays are present, then the cross peak will acquire some net intensity

Figure 7 Magnitude calculation COSY on serine at 500 MHz, but with a mixing pulse of $\pi/4$. All other parameters are as in Figures 4 and 6

Figure 8 Plot of the row of peaks at the bottom (highest f_1 frequency) of the 2D spectrum in Figure 7[trace (b)]. Trace (a) represents a SIMPLTN simulation of the data

and cross peaks due to quite small couplings will be evident in the 2D spectrum.¹⁶

Similarly, poor digitization should cause cross peaks to disappear. If the digitization is such that a single point in two dimensions represents an entire set of cross peaks due to two multiplets, that point should have zero intensity. Very good digitization should give accurate intensities. In between these extremes, however, the behavior is somewhat unusual. When the digitization (in Hz per point) approaches the value of the

coupling constant J (in Hz), simulations show that the apparent intensity of the cross peak rises rather than falls. The apparent intensity reaches a maximum at a ratio of $J/\text{digitization}$ of approximately 1, and there is still significant intensity when the coupling is only 0.2 of the digitization.¹⁷ This effect, combined with the possible use of fixed delays around the mixing pulse, permits us to use quite small data matrices and still see useful correlations.

Provided digital resolution is not a problem, the cross peak between an A spin and an X spin will be as follows. If it is the peak in f_1 which corresponds to the A frequency in f_2 , then the rows will resemble the A spectrum and the columns the X spectrum, as shown in Figure 4. Similarly, the other cross peak will resemble the X spectrum along the f_2 rows and the A spectrum in f_1 . The only difference will be that the splittings due to the A–X coupling will appear as an antiphase, 1: – 1, orientation, but all other couplings will be normal.

2.7 Flip Angle Effects

If we use the simple trigonometric identity given in equation (8), we can see from equation (3) that three of the lines in the simple two-spin COSY behave identically with respect to the flip angle of the mixing pulse. The odd line is the off-diagonal member of the diagonal group of peaks—the peak due to mixing of one line with the other line in the doublet. In Figure 2, we can observe that these are the only pairs of transitions that do not share at least one energy level. All other peaks in the 2D spectrum come from pairs of ‘connected’ transitions.

$$\sin^2 \alpha = 2 \sin^2 \frac{\alpha}{2} (1 + \cos \alpha) \quad (8)$$

Equation (3) predicts that this peak from ‘unconnected’ transitions will decrease in intensity relative to the others as the flip angle of the mixing pulse is decreased. For a flip angle of $\pi/4$, this peak is approximately 17% of the others. Judicious choice of a contour level in the plot of a 2D spectrum will make this peak disappear, so the diagonal region of the spectrum is much cleaner. This is shown by comparing Figures 6 and 7. As Figure 8 shows, the peaks do not disappear.

Another consequence of this shows up in the cross peaks of bigger spin systems. Here also there are peaks due to pairs of unconnected transitions. Depending on the relative signs of couplings, this gives a characteristic ‘tilt’ to the cross peak. This can be used to assign the relative signs of couplings. In an AMX spin system, the tilt of the cross peak between A and M will indicate the relative signs of J_{AX} versus J_{MX} . Figures 6 and 7 show this effect for serine. The cross peak between the two β protons at the high-frequency side of the spectrum tilts one way, since the couplings to the third (α) proton are both vicinal and of the same sign. However the α – β cross peaks tilt the other way because of the opposite signs of the vicinal and geminal couplings.

The use of a different flip angle for the mixing pulse will decrease the intensity of these peaks but it will not eliminate them, as shown in Figures 7 and 8. If the peaks are to be eliminated, then another variation of the simple experiment, ECOSY, should be used.¹⁸ This is more complex to set up, but it will give more reliable and useful intensities. This will be useful, for example, in the automatic interpretation of COSY spectra.

2.8 Strong Coupling Effects

Most homonuclear spin systems show some signs of strong coupling. This is more evident in the intensities of the lines rather than in the line positions. This is because the intensities of the lines are determined by the xy magnetizations of the spin system, which are perturbed to first order by strong coupling. The line positions depend on the energy levels and z magnetizations, which are perturbed only to second order. The general rule that no new frequencies will appear in f_1 in COSY still holds. However, since the COSY experiment involves the mixing of xy magnetizations it is clear that intensities will be greatly affected by strong coupling.

As an example, let us consider a magnitude calculation COSY on a simple AB spin system. In such a system, we need only consider the negative frequency coherences, as in equation (2), and how much is transferred to the positives for detection, as in equation (5). For such a system, it is convenient to define the frequencies of the four lines in the spectrum in the following way. Let ν_0 be the average of the A and B Larmor frequencies, and let δ be the difference of the Larmor frequencies in Hz. If J is the scalar coupling constant between A and B, then we can define $C = (J^2 + \delta^2)^{1/2}$ and an angle, θ , by the relationship $\sin(2\theta) = J/C$. For simplicity of notation, let $c = \cos(\theta)$ and $s = \sin(\theta)$. For simplicity, let us number the frequencies as in equation (9).

$$\left. \begin{aligned} \nu_1 &= \nu_0 + C/2 + J/2 \\ \nu_2 &= \nu_0 + C/2 - J/2 \\ \nu_3 &= \nu_0 - C/2 + J/2 \\ \nu_4 &= \nu_0 - C/2 - J/2 \end{aligned} \right\} \quad (9)$$

With these definitions, we can calculate the evolution of the negative frequencies up to the mixing pulse, as in equation (2), to give equation (10).

$$\left. \begin{aligned} |- \nu_1) &= (c - s)e^{-i(\nu_0 + C/2 + J/2)t_1} \\ |- \nu_2) &= (c + s)e^{-i(\nu_0 + C/2 - J/2)t_1} \\ |- \nu_3) &= (c + s)e^{-i(\nu_0 - C/2 + J/2)t_1} \\ |- \nu_4) &= (c - s)e^{-i(\nu_0 - C/2 - J/2)t_1} \end{aligned} \right\} \quad (10)$$

Note that the coherences do not have equal intensity as was the case in the weakly coupled spin system.

Let us only consider the case of a flip angle of the mixing pulse of $\pi/2$, in order to simplify the calculation somewhat. Using published methods,^{19,20} it is relatively easy to show that the effect of the mixing pulse on the coherences in equation (10) is given by the matrix in equation (11). This is the strong-coupling equivalent of equation (3) for a flip angle of $\pi/2$.

$$1/4 \begin{bmatrix} (c-s)^2 & c^2 - s^2 & c^2 - s^2 & -(c+s)^2 \\ c^2 - s^2 & (c+s)^2 & -(c-s)^2 & c^2 - s^2 \\ c^2 - s^2 & -(c-s)^2 & (c+s)^2 & c^2 - s^2 \\ -(c+s)^2 & c^2 - s^2 & c^2 - s^2 & (c-s)^2 \end{bmatrix} \quad (11)$$

Finally, strong coupling also implies that not all lines are detected with equal intensity. This means that the final intensities are the result of multiplying the coherences in

equation (10) by the matrix in equation (11) and then multiplying by the detection efficiency, as in equation (12).

$$\left. \begin{aligned} |v_1\rangle &= \frac{1}{4}(c-s)[(c-s)^2(c-s)e^{-iv_1t_1} + (c^2-s^2)(c+s)e^{-iv_2t_1} \\ &\quad + (c^2-s^2)(c+s)e^{-iv_3t_1} - (c+s)^2(c-s)e^{-iv_4t_1}] \\ |v_2\rangle &= \frac{1}{4}(c+s)[(c^2-s^2)(c-s)e^{-iv_1t_1} + (c+s)^2(c+s)e^{-iv_2t_1} \\ &\quad - (c-s)^2(c+s)e^{-iv_3t_1} + (c^2-s^2)(c-s)e^{-iv_4t_1}] \\ |v_3\rangle &= \frac{1}{4}(c+s)[(c^2-s^2)(c-s)e^{-iv_1t_1} - (c-s)^2(c+s)e^{-iv_2t_1} \\ &\quad + (c+s)^2(c+s)e^{-iv_3t_1} + (c^2-s^2)(c-s)e^{-iv_4t_1}] \\ |v_4\rangle &= \frac{1}{4}(c-s)[-(c+s)^2(c-s)e^{-iv_1t_1} + (c^2-s^2)(c+s)e^{-iv_2t_1} \\ &\quad + (c^2-s^2)(c+s)e^{-iv_3t_1} + (c-s)^2(c-s)e^{-iv_4t_1}] \end{aligned} \right\} \quad (12)$$

Equation (12) shows the intensities of all the lines in a COSY spectrum of an AB spin system. If we apply the trigonometric identities in equation (13), we can further simplify the expressions.

$$\left. \begin{aligned} \cos^2 \theta - \sin^2 \theta &= \cos 2\theta \\ (\cos \theta + \sin \theta)^2 &= (1 + \sin 2\theta) \\ (\cos \theta - \sin \theta)^2 &= (1 - \sin 2\theta) \end{aligned} \right\} \quad (13)$$

The final expressions for the COSY on an AB system are given in equation (14).

$$\left. \begin{aligned} |v_1\rangle &= \frac{1}{4}[(1 - \sin 2\theta)^2 e^{-iv_1t_1} + \cos^2 2\theta e^{-iv_2t_1} \\ &\quad + \cos^2 2\theta e^{-iv_3t_1} - \cos^2 2\theta e^{-iv_4t_1}] \\ |v_2\rangle &= \frac{1}{4}[\cos^2 2\theta e^{-iv_1t_1} + (1 + \sin 2\theta)^2 e^{-iv_2t_1} \\ &\quad - \cos^2 2\theta e^{-iv_3t_1} + \cos^2 2\theta e^{-iv_4t_1}] \\ |v_3\rangle &= \frac{1}{4}[\cos^2 2\theta e^{-iv_1t_1} - \cos^2 2\theta e^{-iv_2t_1} \\ &\quad + (1 + \sin 2\theta)^2 e^{-iv_3t_1} + \cos^2 2\theta e^{-iv_4t_1}] \\ |v_4\rangle &= \frac{1}{4}[-\cos^2 2\theta e^{-iv_1t_1} + \cos^2 2\theta e^{-iv_2t_1} \\ &\quad + \cos^2 2\theta e^{-iv_3t_1} + (1 - \sin 2\theta)^2 e^{-iv_4t_1}] \end{aligned} \right\} \quad (14)$$

The true diagonal peaks show the expected behavior: the result of mixing a line with itself gives the square of the intensity in the 1D spectrum. However, all the other peaks show the same intensity, even as a result of mixing one low-intensity outer peak with the other outer peak. This is somewhat unexpected, but is shown experimentally in the spectra of serine in Figures 4 and 5.

3 LARGER SPIN SYSTEMS

Larger spin systems can be treated as simple combinations of two-spin systems in most cases. The cross peaks will reflect the structures of the f_1 and f_2 spectra as above, with the proviso about the active coupling being in antiphase. Provided the system is in equilibrium, there will be no new frequencies appearing in f_1 . In strongly coupled systems, the intensities of some individual peaks may be such that they are missing from a contour plot, but a cross peak will still be visible. Some spin systems, such as the ABX system, can be analyzed algebraically, but the calculations can get quite complex even for a simple experiment like COSY. For these systems, computer simulations provide a very useful tool.²¹⁻²⁵ With modern computers, exact density matrix calculations can be done in a few minutes on systems of four or five strongly coupled spins. For example, the simulations for Figures 5 and 8 were undertaken in under 30 s on a 1992 model UNIX

workstation. For systems with several spins, a combination of the basic rules for two spins and some simulations and experience will faithfully predict the quantitative nature of the COSY spectrum.

4 FAST PULSING ARTIFACTS

The statement that no new frequencies appear in a COSY rests on the assumption that the spins relax completely between pulse sequences, and this is almost never true in practice. Under normal circumstances, artifacts that are derived from the f_2 frequencies will appear in the spectrum. Usually these appear as peaks at $f_1 = 0$, small P-type peaks which have not been totally suppressed or peaks at multiples of the f_2 frequency. These are especially evident for strong singlets due to methyl groups, which often have long relaxation times. These artifact peaks can be minimized by doing dummy scans before the actual acquisition, in order to get the spin system into a steady state. Also, careful attention to the phase cycling sequence and how one experiment interacts with the next can be very helpful.^{26,27} Also, the use of magnetic field gradients, rather than phase cycling, to select coherence pathways is very effective in reducing the artifacts due to incomplete relaxation.

5 CONCLUSIONS

The COSY experiment serves as the best example of two-dimensional NMR spectroscopy. In its many forms it is an extraordinarily useful experiment, and yet it is quite simple to analyze and understand. The two-spin systems described here illustrate almost all the important features of the experiment. A few pages suffice to describe these systems completely and quantitatively, so it is well within the reach of all NMR spectroscopists. This combination of simplicity and power makes the COSY experiment stand out.

1 INTRODUCTION

Quantitative analytical measurements have been dominated for many years by optical spectroscopy in the infrared, visible, and ultraviolet regions of the electromagnetic spectrum. Such instruments have become the basis for a large number of routine analytical procedures, especially in the chemical and pharmaceutical industries and in medicine. Stability problems, which plagued early instruments prior to the development of solid state electronics in the 1950s, have been largely overcome, and the relative small size, low cost, simplicity of operation, and reproducibility of results have led to widespread reliance on optical spectrometers in analytical and chemical laboratories.

Nuclear magnetic resonance spectroscopy has also been used as a quantitative analytical tool since the early 1950s, shortly after its discovery. However, it has not achieved the same degree of user confidence and widespread routine application as optical spectroscopy. Perceived as a large, expensive, complex, unfriendly, and marginally stable instrument, NMR has tended to be used as a last resort when other quantitative methods fail. However, continuous improvement of NMR instrumentation over the past 40 years has gradually narrowed the differences and even reversed some of those perceptions. NMR is now in a position to be considered seriously for a wide range of analytical and clinical applications, and even regarded as the method of choice for some analyses.

Above and beyond the role that quantitation of NMR measurements can play in the analytical laboratory is the application of such measurements to the assignment and interpretation of NMR spectra used for the determination of molecular structure. The complexity of such problems often requires that the NMR spectroscopist utilize all the information in the spectra, including the quantitative relationships that exist between the peaks and multiplets, arising from the various nuclei in the sample. Internuclear distance measurements, necessary for

establishing molecular conformation, depend upon quantitative measurement of nuclear Overhauser enhancement (NOE). Because of the reputation of NMR as the most effective physical tool for structure determination, that aspect of quantitative NMR spectroscopy may well achieve more importance than the less glamorous analytical applications.

2 ADVANTAGES AND DISADVANTAGES AS AN ANALYTICAL TOOL

NMR spectroscopy excels in the measurement of relative amounts of the components of a mixture. One reason for this is that the absorption coefficient for the absorption of electromagnetic energy is essentially identical for all nuclei of the same species in a molecule or mixture of molecules. In contrast, the absorption coefficient in optical spectroscopy must be calibrated (by measurement) for each spectroscopic transition assigned to the various components of the mixture, because the coefficient is a complex function of transition probability, energy differences, and perturbations of the energy level system. Thus, while an analysis of the relative amounts of the components in a mixture can be carried out by NMR without ever separating the mixture into its components or having authentic samples of them, the absorption coefficients must either be known or measured before such an analysis can be performed in the optical region.

A second advantage for NMR spectroscopy in mixtures arises from the effective isolation of the nuclei from forces acting on the molecules, leading to linewidths many orders of magnitude less than those in the optical range. The effective resolution of NMR spectrometers, particularly since the widespread incorporation of high-field superconducting magnets, is far better than their optical counterparts, often resulting in little or no interference or overlap of the analytical peaks.

Whether a particular behavior of a system is viewed as an advantage or a disadvantage depends upon what one is trying to accomplish. A highly absorbing substance can confer superiority on the optical spectroscopic analysis for trace amounts of that substance, or make minor fluctuations in the amount of it a disastrous source of error in the measurement of something it overlaps. The uniformly low sensitivity of NMR spectroscopy relative to optical spectroscopy, which arises from the low frequency of NMR transitions compared with the electronic, vibrational, and rotational transitions in the optical range, has placed NMR at a significant disadvantage for analyses of trace amounts, which are easily overwhelmed by the signals from the major components of a mixture or may even be too weak to distinguish from the random background noise of the instrument.

The timescale of NMR events is in the range of seconds to milliseconds, and, occasionally, microseconds, while optical events occur in the nanosecond and picosecond range. That has a profound effect on the ability to measure transient species, which must have a much larger half-life to be measurable by NMR than by optical spectroscopic methods.

Both optical and NMR spectrometers can be used to good effect in the analytical laboratory. The task of the analyst is to pick a method that utilizes the strengths and minimizes the weaknesses of the type of instrument chosen to perform a given analysis.

3 THEORY

Until the 1970s, nearly all high-resolution NMR spectrometers operated in the field-swept mode, and small, low-cost, permanent magnet instruments of that type continue in production up to the present time. Adjustment of the phase-sensitive detector in such instruments permits selection of either the absorption (v) or dispersion (u) component of the NMR signals.

Owing to its sharpness and suitability for integration, the absorption component is generally selected for quantitative measurements. Assuming slow passage conditions, i.e., a sweep rate dB/dt small enough to ensure that the time to traverse each of the NMR signals is much longer than the longitudinal and transverse relaxation times (T_1 and T_2), the integral of the absorption component given by the Bloch equations¹⁻³ is

$$\int v dB = \frac{(\text{const})M_0B_1}{[1 + (\gamma B_1)^2T_1T_2]^{1/2}} \quad (1)$$

where M_0 is the net nuclear magnetic moment, B_1 is the exciting radiofrequency field strength, and γ is the magnetogyric ratio. Mathematically, the integral is evaluated from 0 to infinity, but in practice need only be measured over a range sufficient to include all the area under the peaks within the desired accuracy of the measurement.

Numerical integration of the peak intensities plotted as a function of magnetic field, i.e., the total area under the signals arising from the species to be measured, has been used, but such methods involving counting squares, cutting out and weighing, or using a planimeter, are extremely unwieldy and subject to large errors. It is much better to measure the integral as a function of time, using an electronic integrator to sum the output voltage of the detector over the time of passage through the signals. That integral is given by the expression

$$\int v dt = \frac{(\text{const})M_0B_1}{(dB/dt)[1 + (\gamma B_1)^2T_1T_2]^{1/2}} \quad (2)$$

where the sweep rate dB/dt is the rate of change of the field strength per unit time.

Since M_0 depends upon the number of nuclei per unit volume, N , and upon the excess population in the lower Zeeman level, which at room temperature is inversely proportional to the absolute temperature T , the integral becomes

$$\int v dt = \frac{(\text{const})B_1N}{T(dB/dt)[1 + (\gamma B_1)^2T_1T_2]^{1/2}} \quad (3)$$

Under the slow passage conditions required for the validity of equation (3), if B_1 , T , and dB/dt are kept constant, the integrals will be reproducible, but will depend upon the relaxation times T_1 and T_2 . If, however, $(\gamma B_1)^2T_1T_2 \ll 1$, the integrals become independent of relaxation, and are an accurate measure of the concentration. That requires making B_1 small, and, because the integral is proportional to B_1 , the signal-to-noise ratio may limit the accuracy of the measurement before the slow passage condition can be met. That is generally the case except for very broad lines (small T_2) or strongly interactive nuclei (short T_1).

Another difficulty in meeting slow passage conditions arises from the requirement that dB/dt be small if the lines are narrow, allowing magnetic field drift or other instabilities to become comparable to dB/dt and become significant sources of error. The time consumed in a single scan through the full spectrum can also become inconveniently large, especially at high magnetic field strengths.

Such practical considerations dictate that chosen values of B_1 and dB/dt often violate the slow passage condition. Jacobsohn and Wangsness⁴ modified the Bloch equations to take into account the transient response of the nuclei at faster sweep rates. They found that an oscillatory decay term must be added. That results in *wiggles* following sharp lines in most field-swept high-resolution spectra, but the oscillatory term contributes no area unless it is truncated.

The term $[1 + (\gamma B_1)^2T_1T_2]^{1/2}$ in equation (3) represents the effect called *saturation*, and is proportional to the decrease in the excess population of the lower Zeeman level over the time interval T_1 required for slow passage during which transitions occur with the probability $(\gamma B_1)^2T_2$. An approximation to the behavior for more rapid passage conditions is obtained by replacing T_1 by the actual time of passage, $\Delta B (dB/dt)^{-1}$. Because the linewidth ΔB is $1/\gamma T_2$, equation (3) is modified to

$$\int v dt = \frac{(\text{const})B_1N}{T(dB/dt)[1 + \gamma B_1^2(dB/dt)^{-1}]^{1/2}} \quad (4)$$

The expression $1/(1+x)^{1/2}$ can be expanded to $1 - \frac{1}{2}x + \dots$ for small x , where $x = \gamma B_1^2(dB/dt)^{-1}$, giving

$$\int v dt = \frac{(\text{const})B_1N[1 - \frac{1}{2}\gamma B_1^2(dB/dt)^{-1} + \dots]}{TdB/dt} \quad (5)$$

and consequently

$$\int v dt \rightarrow \frac{(\text{const})B_1N}{TdB/dt} \quad (6)$$

if $\gamma B_1^2/(dB/dt) \ll 1$. Equation (6) predicts that, even at high rf power levels, the integrals can be made essentially independent of relaxation times for sufficiently fast sweep rates.

It would appear that a signal-to-noise problem might arise, since, in order to keep $\gamma B_1^2/(dB/dt) \ll 1$, an n -fold increase in sweep rate can only be accompanied by a $\sqrt{n}$ -fold increase in B_1 , resulting in an integral smaller by $\sqrt{n}$. However, an n -fold faster sweep permits obtaining n times as many observations per unit time, and statistical averaging of n observations restores the factor $\sqrt{n}$ in the reliability of the result. The smaller integrals need to be measured rapidly and to three decimal places, making a digital voltmeter the preferred method of reading the integrals if integration for analytical purposes (1.0% or better) is the object.

An additional benefit of obtaining a statistically significant number of independent measurements of the integral arises from the possibility of estimating the confidence limits (standard deviation) of the results. Thus, a determination of the precision of the measurement can be obtained along with the measurement.

4 ACCURACY OF CW NMR INTEGRAL MEASUREMENTS

Using a sweep rate of $5\text{--}10\text{ Hz s}^{-1}$ for integrating instead of the usual $0.5\text{--}2\text{ Hz s}^{-1}$ for recording the absorption-mode high-resolution spectrum reduces the errors from random drifts in the magnetic field correspondingly, and in modern thermally stabilized permanent magnet systems should permit integration accuracy better than 1.0%. To achieve this, however, another source of error must be eliminated. That error is due to variation in the dc output of the rf detector, arising from instabilities in probe balance, dc amplifier balance, and stray coupling in cables and leads. The problem is greatly reduced by the use of audiofrequency modulation of the magnetic field at a frequency of 1 or 2 kHz. Several authors^{5–7} have discussed the effect of such modulation on the NMR signals. A set of audiofrequency sidebands are obtained along with an audiofrequency signal at the usual field strength. By suitable adjustment of modulation amplitude and phase, the sidebands can be rejected, essentially completely, by a phase-sensitive detector, while the centerband signal, now free from low-frequency drifts after traversing an *RC* coupling circuit, is converted back to dc, recorded, and integrated.

The author performed tests to verify the validity of equation (6) in application. A fairly stringent test involved the determination of the total percentage of hydrogen by weight for several samples (25 mg) of pure organic compounds, compared with a standard sample of naphthalene (C_{10}H_8). Measurements of three standard samples (A, B, and C), and three complex natural products of molecular formulas $\text{C}_{27}\text{H}_{44}\text{O}_3$, $\text{C}_{15}\text{H}_{18}\text{O}_6$, and $\text{C}_{15}\text{H}_{20}\text{O}_6$ were made, and are shown in Table 1. The three standards were assigned the theoretical value of 6.29% hydrogen in column 3, and the measured values, which average 6.29, are shown in column 4. The three test compounds were run under the same experimental conditions, and their theoretical and observed percentages of hydrogen by NMR are compared in columns 3 and 4.

Table 1 Total Hydrogen Analyses by NMR for Complex Organic Molecules

Sample	Weight (mg)	%H by weight	%H (NMR) ^a
C_{10}H_8 (A)	25.1	6.29	6.31 ± 0.03^b
C_{10}H_8 (B)	25.3	6.29	6.28 ± 0.01
C_{10}H_8 (C)	25.3	6.29	6.28 ± 0.02
$\text{C}_{27}\text{H}_{44}\text{O}_3$	25.1	10.65	10.58 ± 0.05
$\text{C}_{15}\text{H}_{18}\text{O}_6$	25.2	6.26	6.27 ± 0.04
$\text{C}_{15}\text{H}_{20}\text{O}_6$	25.1	6.80	6.81 ± 0.03

5 PULSED FOURIER TRANSFORM NMR

Beginning in the 1970s, the pulsed Fourier transform mode of operation began to supplant the CW mode of operation, especially for superconducting magnet systems operating at high magnetic field strengths. Owing to the great improvement in sensitivity arising from simultaneous wideband excitation of all nuclei in the sample, and the flexibility of time domain detection, which makes two-dimensional NMR spectroscopy

possible, FT NMR has completely replaced CW NMR except as noted at the beginning of Section 3. Workers with modern equipment will therefore find the following treatment of quantitation more relevant to their needs than the preceding one.

Following a short pulse of rf magnetic field in a coil surrounding the sample, the nuclei, which resonate in a band of frequencies (arising from the chemical shift) around the pulse frequency, are found initially precessing in a state of phase coherence and with altered populations of the upper and lower energy states. The system can be described as a set of precessing magnetization vectors, tipped (or rotated) away from the magnetic field (*z*) axis by an amount determined by the field strength and duration of the pulse. Each vector consists of all of the nuclei that contribute to the corresponding spectral line in the frequency (or magnetic field) spectrum. The receiver is turned on, and the system is allowed to precess freely, inducing sinusoidal voltages in the receiver coil. The resulting free induction decay (FID) is the interferogram of all those sine waves, decreasing exponentially with time as phase coherence is lost at the relaxation rate T_2^{-1} . Digitization of the interferogram and storage in a computer memory allows the waveform to be subjected to Fourier transformation, which generates the slow passage NMR spectrum.⁸

During the data acquisition, the field strength is held constant, using the deuterium nuclei in the solvent as the source of an error signal to correct the infinitesimal drifts in the superconducting magnet field strength or shifts in the master-clock controlled frequency. Multiple acquisitions can then be added together digitally to improve the signal-to-noise ratio.

The Bloch equations applicable in CW NMR are derived for an equilibrium between the perturbing effect of the exciting rf field and the restoration of magnetization by relaxation processes. In pulsed FT NMR, there is no rf field present during data acquisition; consequently, the situation is greatly simplified. The transformed FID reproduces the static spectrum faithfully, and can simply be integrated numerically from the digital representation of the spectrum. The phase parameters should be adjusted to display the pure absorption, or *v* mode, and then the integral of the transformed spectrum from the FID following a single pulse is given by the expression

$$\int v \, dB = \frac{(\text{const})N}{T} \cos \theta \quad (7)$$

where θ is the tip angle through which the magnetization has been rotated by the rf pulse. A 90° tip angle is often chosen for quantitative work to maximize the integral.

Equation (7) appears deceptively simple, and may give the impression that integration of FT NMR spectra is inherently more accurate than integrals from CW NMR. It is best to reserve judgment on that point until consideration is given to the possible sources of error in FT NMR quantitation.

6 SOURCES OF ERROR IN FT NMR INTEGRAL MEASUREMENTS

Filter bandwidth response is a common source of error. The sampling rate or digitization rate during data acquisition determines the width of the band of frequencies centered on

the pulse frequency that can be identified from the digital samples by Fourier transformation. It is common to insert a filter in the circuit to reject all voltage fluctuations of higher frequency than this spectral width in order to avoid the folding-in of noise from regions immediately adjacent to both sides of the spectral window. Unfortunately, filters with a very steep cut-off characteristic cause troublesome phase shifts, and a compromise is made by choosing a more gradual roll-off, which begins to attenuate noise (and signals) near the ends of the range defined by the spectral width. Thus, NMR signals that are near either end of the spectrum may give a low result. It is normally possible to deactivate the filter or to choose a value for the filter bandwidth larger than the spectral width in such cases to avoid attenuating NMR signals, but at a sacrifice of about a factor of two in the signal-to-noise.

A more fundamental source of error can arise from the profile of excitation associated with a pulse of rf magnetic field. For a perfect pulse with a rectangular shape and instantaneous rise and fall times, the energy distribution over a range of frequencies is described by a Bessel function involving the reciprocal of the pulse length. Thus, very short pulses give a flat power distribution around the pulse frequency and fall off far from the pulse. For nuclei with a small range of chemical shifts, such as ^1H and ^{13}C , most modern commercial NMR instruments supply enough pulse power to achieve a 90° tip angle in a pulse of $10\text{ }\mu\text{s}$ or less. That makes the energy distribution an insignificant source of error, since all nuclei within the spectral width experience essentially the same tip angle. In the case of ^{19}F and other nuclei with chemical shifts of several thousand ppm, it may be necessary to shorten the pulse length and accept the loss in sensitivity resulting from a smaller, but more constant, tip angle over the spectral range.

Another source of error is pulse breakthrough and acoustic ringing. The receiver is turned off for a few microseconds after the pulse to allow recovery of the tuned circuit from the induced current. Sometimes, when the receiver is first turned on, those currents have not died away completely or have excited acoustic modes in the probe structure that decay more slowly and result in distortion of the first several data points in the FID. Those points transform to a very broad roll in the baseline, which requires the operator to make some subjective judgments about the type of baseline correction routines to apply. The simplest baseline correction routine for that situation is a correction in which a linearly increasing or decreasing amount is subtracted from each successive data point, adjusted by the computer to set the endpoints to zero. That type of software correction often works well over a narrow spectral range, e.g., a few linewidths on either side of a sharp line, but over a wider range it is usually not adequate to deal with the complex shapes arising from transient distortions, particularly if the NMR signals are weak. These transform into 'rolling' baselines with hills and valleys that cannot be corrected with a simple linear function.

Commercial NMR instruments often include more elaborate baseline correction routines that allow the operator (or, better yet, the computer) to identify and specify regions representing baseline, alternating with regions containing NMR signals. All of the baseline regions can be set to zero and the signal-containing regions joined smoothly to them with a software command. In well-resolved spectra, integral accuracy can be greatly improved by that means.

If the tails of the signals overlap, or if the operator makes subjective errors in judging where the tails cease to contribute significantly to the integrals and thereby defines the baseline regions incorrectly, errors may be introduced. Integrating the spectrum many times with independent baseline corrections, or using several operators, allows statistical reduction of random baseline correction errors, but it does not eliminate systematic errors from operator bias.

A recent advance in dealing with such problems is the technique of *linear prediction*,⁹ by which the FID waveform can be extended in either direction in time, based on the data obtained during the acquisition. The early data points can be discarded and replaced with data points reconstructed from the rest of the data, after which baseline correction requirements are minimal.

7 STABILITY AND LINEARITY OF SPECTROMETER HARDWARE

Phase and amplitude instabilities of the rf pulses were significant sources of error in early FT spectrometers, but major manufacturers have greatly improved amplifier performance in modern instruments and have reduced such errors to the point of insignificance. Since errors of that type tend to be random, they can be further decreased by making a series of independent measurements.

Modern instruments also have built-in safeguards against overflowing the digital memory channels of the computer, and are linear over a large dynamic range. Older instruments may require vigilance on the part of the operator to ensure that amplifier gains are set properly.

8 APPLICATIONS

The ability to integrate accurately leads to the solution of a variety of physical organic chemical problems and analytical problems. By the end of the 1960s, a number of examples were available.

8.1 Analysis of Rapidly Equilibrating Mixtures

A remeasurement of the ratio of keto to enol forms of the tautomeric mixture of the two, first reported by Jarrett, Sadler, and Shoolery¹⁰ in 1953, illustrates the excellent precision of the analysis using the CW methodology described in Sections 3 and 4. Figure 1 shows the spectrum and integral with typical digital voltmeter readings for the steps *a*, *b*, and *c*, corresponding to the olefinic proton of the enol form, the two methylene protons of the keto form, and the methyls in both forms. The percentages of keto and enol can be easily calculated, as shown in Figure 1.

A series of five repeated measurements allowed a statistical evaluation of the precision of the measurement, giving standard deviations of 0.4% for the keto and 0.7% for the enol content. Since the system remains in equilibrium during the measurement, a more accurate measurement of the equilibrium constant is possible than that obtained from bromine titration.

Figure 1 Analysis of a tautomeric mixture

8.2 Monitoring Purification and Separation Processes

Coenzyme Q₁₀ has the structure shown in Figure 2, where the number of isoprene units in the side chain is $n = 10$. Separation of compounds with 9 or 11 units is difficult. The absence of such contaminants in the sample is confirmed by the ratio of the area arising from the six protons of the two methoxy groups to the area of the peak at 5.0 ppm that contains a proton from each repeated unit. The average number of units in the chain is found to be within 0.2% of the expected value of 10.

8.3 Iodine Value of Fats and Oils

Johnson and Shoolery¹¹ showed in 1962 that the number of protons attached to doubly bonded carbons could be determined from the proton spectrum of edible oils consisting of various triglyceride mixtures of mono-, di-, and tri-unsaturated C₁₈ fatty acids. Each fat or oil molecule contains five protons attached to the three carbon atoms of the glyceryl chain. Four of these are the CH₂ protons in the 1,3 positions, which give a multiplet centered at 4.2 ppm, and the fifth (the proton on C-2) gives a multiplet at 5.3 ppm that is not resolved from the olefinic protons found between 5.2 and 5.3 ppm. In the 200 MHz spectrum of corn oil, shown in Figure 3, the integral over the region from 5.6 to 5.0 ppm between points 1 and 2 represents the olefinic protons plus the proton on C-2, while the integral of the 4.5–3.9 ppm region between points 2 and 3 represents four protons per molecule of oil. If these two integrals are designated A and B , respectively, it follows that the number of olefinic protons (and doubly bonded carbons), N , per molecule of oil is $4A/B - 1$.

The degree of unsaturation is routinely measured by titrating the oil with iodine. The uptake of iodine at the endpoint

is expressed as the iodine value (IV), and is the number of grams of iodine consumed by 100 g of fat. There is an exact correspondence in the number of iodine atoms per molecule at the completion of the reaction and the number of olefinic protons in the original fat. This leads to the expression

$$IV = \frac{12691N}{\text{Mol. wt. of fat}} \quad (8)$$

and if the fat consists entirely of C₁₈ fatty acid triglycerides, equation (8) becomes

$$IV = \frac{12691N}{890.88 - N} \quad (9)$$

This formula can be corrected for oils containing fatty acids with a variety of chain lengths if the total integral of the proton spectrum is also measured.

The modern 200 MHz superconducting FT NMR spectrometer used for this analysis was programmed by standard keyboard commands to execute a macro command when instructed by pressing a function key. After automatic locking and shimming, the spectrometer acquired the spectrum, processed the FID, and performed numerical integration of regions A and B . The integrals were stored, and the IV was calculated and printed on the chart and on a printer. Thus, rapid, nondestructive analysis of small samples (50–100 mg) of fats and oils by proton NMR, requiring no special operator skills or judgment, can be regarded as routine.

9 QUANTITATION IN ¹³C NMR

Quantitative measurements in ¹³C NMR are complicated by the fact that two techniques that are necessary to improve

Figure 2 Determination of chain length of coenzyme Q₁₀ (Molecular weight 862.7)

sensitivity and resolution can strongly perturb the populations of the ¹³C nuclear energy levels. The integrated intensities of the NMR peaks will then depend on factors other than the number of nuclei giving rise to the peak. Fortunately, methods for restoring the equilibrium magnetization can be employed to circumvent this problem.^{12,13}

9.1 Time Averaging of Multiple Data Acquisitions

This technique is used in all FT NMR spectrometers whenever the signal-to-noise ratio needs to be improved, or when phase cycling is required to suppress artifacts. If the magnetization is not allowed to recover fully after each pulse, the next acquisition will reflect the decreased magnetization. That process will continue until an equilibrium is reached, which depends upon the relative values of the spin-lattice relaxation time T_1 for each transition, the pulse tip angle, and the pulse repetition rate. The integrals no longer depend only upon the number of nuclei. The problem occurs in all time-averaged FT NMR spectra, regardless of the nucleus being studied, but is much more troublesome for ¹³C NMR, because of the long T_1 values found for ¹³C in a variety of chemical environments.

There are three ways to remedy this situation.

1. One can introduce a recovery delay between pulses long enough to result in complete repolarization of even the

nuclei with the longest T_1 . This may require several hundred seconds, and can therefore result in very long total accumulation times.

2. One can use a very short pulse, which perturbs the population of the spin states very little.
3. One can dissolve a paramagnetic material in the sample to make all T_1 values short compared with the pulse repetition rate.

9.2 Broadband Proton Decoupling

Broadband decoupling involves irradiating all protons in the sample with an intense rf magnetic field at their resonance frequency so that their spins are effectively decoupled from the ¹³C nuclei and the latter consequently appear with all of their intensity in a single sharp line rather than a widely split multiplet of many weak lines. That technique has been a major factor in the successful application of ¹³C to solving chemical problems. An auxiliary benefit has been a badly needed gain in sensitivity, as a result of nuclear Overhauser enhancement (NOE). Strong irradiation of the proton transitions in a coupled spin system perturbs the populations of the spin states involved in the carbon transitions, and results in an increase in the peak intensity to a value 2.988 times the Boltzmann value. Unfortunately, the excess population generated in this manner can leak off if the ¹³C nuclei can exchange energy with their

Figure 3 200 MHz proton spectrum of corn oil

surroundings in other ways. This can lead to a range of NOE values for carbons in the same molecule from 1.0 to 2.988, and invalidates quantitative comparison of integrals.

There are also three ways of dealing with the problem of variable NOE factors.

1. One can operate without proton broadband decoupling. This has the disadvantage that the reappearance of the rather large proton–carbon scalar couplings will cause severe overlap of the ^{13}C spectral regions of interest. Furthermore, the usual gain in sensitivity due to NOE will not be realized.
2. One can gate the decoupler on during the acquisition of data and off during the rather long delay necessary to avoid relaxation recovery effects. The build-up of excess ^{13}C population during acquisition will die away again during the delay period. Of course, the sensitivity will suffer because of the loss of the NOE, but the ^{13}C signals will be collapsed into sharp peaks, with all of the intensity for each carbon in a single line.
3. One can provide an alternative relaxation mechanism for all ^{13}C nuclei in the molecule. Except possibly for ^{13}C atoms deeply buried within a large rigid molecule, it appears that the addition of a paramagnetic species can quench the NOE for all of the carbon atoms without unduly broadening the lines.¹⁴

From the foregoing, two approaches emerge as possible ways to deal with the difficulties arising from unequal T_1 values and NOE values.

1. The decoupler can be gated on only during the acquisition time, and off during a repolarization time chosen long enough to be 4–5 times as long as the longest T_1 .
2. One can add approximately 0.1 M chromium acetylacetonate $[\text{Cr}(\text{AcAc})_3]$ to the CDCl_3 solution of the sample, to shorten all T_1 values and quench all NOE effects. If the acquisition time is not 4–5 times longer than the shortened T_1 then a repolarization delay will also be needed.

10 APPLICATIONS OF ^{13}C NMR

Several examples of the utility of quantitative measurements of ^{13}C spectra in various branches of chemistry illustrate the wide range of applications.

10.1 Structure of an Unknown Hydrocarbon

A hydrocarbon found in a sample of cod liver oil was found to have ten ^{13}C peaks. Spectral editing showed two CH carbons, five CH_2 carbons, and three methyl carbons.

That leads to the unacceptable formula $C_{10}H_{21}$, which violates the bonding requirements and is impossible to reconcile with the proton spectrum. A quantitative experiment using a 30 s recovery delay and gated decoupling to eliminate NOE effects showed conclusively that one of the CH_2 carbon peaks exhibits exactly half the intensity of the other nine carbons. That means that the molecule is *symmetrical* and has two C_9 fragments attached to a unique CH_2 group. That leads to the acceptable formula $C_{19}H_{40}$, and the structure of the hydrocarbon pristane can easily be deduced from the chemical shifts. This compound may be produced by photochemical or thermal rearrangement in storage of cod liver oil, since it has the carbon skeleton (1)

of the side chain in the tocopherols present in cod liver oil.

10.2 Aromaticity of Petroleum Mixtures

Crude oil varies greatly in the ratio of aliphatic (and alicyclic) carbon atoms to aromatic carbon atoms in various substituted and fused ring configurations. A quantitative measurement of this ratio is of considerable value in the industry to obtain the most useful products from a given crude. A sample of crude oil was run with a 200 s delay and gated decoupling, since it was known that carbons at aromatic fused ring junctions can be quite isolated and exhibit a long T_1 . The value of 1.75 obtained for the aliphatic-to-aromatic carbon ratio was then compared with the value of 1.73 obtained by doping the chloroform solution of the oil with 0.1 M $Cr(AcAc)_3$ and running the spectrum under standard conditions. Both methods appear to have eliminated discrepancies from T_1 and NOE effects, but the $Cr(AcAc)_3$ doping enjoyed a time advantage of nearly a factor of 10, and is clearly the choice for repetitive routine analyses. Oils with olefin content would need to be corrected by proton NMR measurements, since the chemical shifts of olefinic and aromatic carbons fall in the same range.

10.3 Analysis of Edible Oils and Seeds

A hypothetical triglyceride composed of oleic acid (18 : 1) and linolenic acid (18 : 3) at the 1 and 3 positions of the glycerol molecule, and linoleic acid (18 : 2) at the 2 position, is shown in Figure 4, along with the ^{13}C spectrum of linseed oil, which contains all three acids along with stearic (18 : 0). The acids may be randomly distributed on the glyceride chains in linseed oil (although the biochemical synthesis in living organisms may be selective), but the ^{13}C spectra are not very sensitive to positional effects. Sixteen peaks or regions can be integrated, and have been assigned contributions from the various carbons in all 18 positions along the fatty acid chains of all four types of fatty acids. Some peaks measure a fatty acid component directly, e.g., B, E, and O represent the C_{16} , C_{15} , and C_{17} carbons, respectively, in 18 : 3, while L represents C_{11} and C_{14} in 18 : 2, overlapped by C_{11} of 18 : 1. All 16 integrals overdetermine the analysis of the four acids, and the best result is obtained by iterating to a least squares fitting of

all the data by adjusting a starting composition to minimize the error. The starting set is estimated from the peaks that are most sensitive to the three unsaturated acids, peaks B, C, E, O, H, and I.

Oil samples were dissolved in $CDCl_3$ and doped with 0.04 M $Cr(AcAc)_3$. The T_1 values were all 1.0 s or less, allowing a 5 s recovery delay with gated decoupling. Table 2 shows the comparison of the ^{13}C NMR analysis with the GC analysis for five widely used vegetable oils. The excellent agreement gives confidence that the relaxation and NOE factors have been eliminated and that the baseline correction and numerical integration routines are obtaining accurate peak areas.

While ^{13}C NMR is not competitive with GC in the analysis of oils expressed from seeds, it is the only way that a noninvasive measurement of oil composition can be made in a viable seed. The oil in seeds is present as a liquid dispersed throughout the seed membranes in minute cavities. The spatial variations in magnetic susceptibility throughout the seed result in significant line broadening due to local dipolar fields, but these can be averaged out completely by spinning the seed about an axis inclined to the magnetic field at the magic angle used in studies of solids by NMR.

11 QUANTITATION OF OTHER NUCLEI

11.1 Nuclei with Spin $\frac{1}{2}$

Other nuclei with nuclear spin- $\frac{1}{2}$, such as ^{31}P and ^{19}F , pose essentially the same problems that have been covered for protons and ^{13}C . The larger range of chemical shifts may, in a few cases, require attention to the uniformity of excitation over the spectral width, and pulsewidths or power may have to be decreased. The strong magnetic moments and 100% abundance of both ^{31}P and ^{19}F make them strong candidates for stable isotope tracers in biological and biochemical studies. Furthermore, the ubiquitous occurrence of ^{31}P in living organisms and the increasing applications of *in vivo* ^{31}P spectroscopy in medicine will surely lead to greater and greater need for accurate quantitative assays based on the general procedures discussed in previous sections.

A study of organophosphorus insecticides in 1977 concluded that ^{31}P NMR provides a very rapid method of analyzing technical samples of these insecticides for both fenitrothion and its artifacts, some of which are present at levels below 0.1%.¹⁵ While both GC and LC are unable to determine some of the possible phosphorus compounds present in technical fenitrothion samples, owing to lack of volatility or nonabsorbance in the UV, the ^{31}P NMR method analyzes for all the phosphorus artifacts. Although the initial cost of the NMR instrumentation is high, the speed of ^{31}P NMR analysis and its use with any organophosphorus insecticide may well be justified when the number of samples is high.

11.2 Nuclei with Spin Greater than $\frac{1}{2}$

Many isotopes of common elements have adequate magnetic moments for NMR detection, but possess other unfavorable nuclear properties that make them unsuitable for NMR studies.

Figure 4 ^{13}C spectrum of linseed oil

Low abundance is often a problem, followed in nuclei with spin greater than $\frac{1}{2}$ by line broadening arising from very short spin–lattice relaxation times. If the nucleus has a spin greater than $\frac{1}{2}$, it possesses a nonspherical distribution of electric charge, manifested by an electric quadrupole moment, which can interact very strongly with fluctuating electric field gradients at the nucleus.

That relaxation mechanism can be a benefit in making quantitative measurements, acting, as it were, like a built-in relaxation agent. Nuclei such as ^7Li , ^{11}B , ^{17}O , ^{23}Na , and several others fall into that category. If, however, the quadrupole moment is too large, which is frequently the case in the heavier elements, or if the type of bonding typical of the element results in a strong ionic component to the bonds it forms, the relaxation times may be in the microsecond range, and the linewidths may be of the order of megahertz. The lifetime of the FID becomes so short that only a few data points can be obtained, and the NMR signals cannot readily

be distinguished from artifacts due to pulse breakthrough and acoustic ringing of the probe structure. Future improvements in hardware may alleviate those problems to some degree, but the best advice for anyone seeking to study the NMR behavior of elements whose nuclei have spin greater than $\frac{1}{2}$ is to check the electric quadrupole moment and compare with ^{17}O . If it is 10–100 times larger then detecting the signals may be next to impossible, and accurate quantitation is out of the question.

12 CONCLUSIONS

While quantitation in NMR spectroscopy is more dependent on control of experimental conditions than is the case in optical spectroscopy, modern NMR spectrometers are sensitive, stable, and relatively user-friendly. The requirements for accurate quantitation in NMR are now well understood and can be met quite easily given the flexibility of the software

Table 2 Fatty Acid Composition of Oils by ^{13}C NMR^a

Component	Rapeseed	Cottonseed	Peanut	Soybean	Safflower

in commercially available instruments. The biggest barrier to widespread analytical use of NMR is the cost, which can make some analytical applications less cost-effective than other alternatives. In research applications, however, the ability to make accurate quantitative measurements adds one more dimension to the utility of an instrumental technique that has proved itself indispensable in every branch of organic chemistry and biochemistry.

1 INTRODUCTION

The term 'adsorbed' implies concentrated at an interface. This article deals with the NMR of small molecules adsorbed, i.e. bound, to solid surfaces. (For a general introduction to adsorption and the properties of surfaces, see Adamson¹ or Somorjai.²) In addition to being of intrinsic scientific interest, adsorbed layers are of great practical importance in the areas of heterogeneous catalysis, separation science, and chromatography.

Molecules may bind to surfaces by any type of interaction, ranging from chemical bonding to van der Waals interaction. The case of chemical bonding is often called 'chemisorption', while the term 'physisorption' is sometimes used for weaker interactions. An adsorbed layer one molecule thick is called a 'monolayer' and thicker adsorbed deposits are called 'multilayers'. Clearly temperature is a major factor in determining the extent of adsorption, and appreciable adsorption will only be found when the interaction energy is greater in magnitude than kT .

NMR is the least sensitive of the common spectroscopic techniques, and thus the observation of adsorbed monolayers is dependent upon having a large amount of surface area in the NMR sample. The surfaces of highest specific area are those of activated carbon, and refractory oxides such as SiO_2 and Al_2O_3 . Because of their great importance as adsorbents, catalysts, and catalyst supports, the preparation of these has been much studied.^{3,4} These substances are readily prepared with specific surface areas of the order of hundreds of square meters per gram ($\text{m}^2 \text{g}^{-1}$). Their densities as powders are typically about 1 g cm^{-3} , so an NMR sample may contain hundreds of $\text{m}^2 \text{cm}^{-3}$. A monolayer of moderate sized molecules might contain $5 \mu\text{mol m}^{-2}$, so that the bulk concentration of an adsorbed monolayer can be of the order of 0.5 M. Such concentrations of sensitive high-abundance nuclei, e.g. ^1H , ^{19}F , and ^{31}P , can be observed in a single

scan with modern instrumentation. Those familiar with liquid NMR will find the effective sensitivity for adsorbed species to be considerably less, due to the much broader lines which arise for reasons noted below. None the less, high sensitivity nuclei are easily observed on such solids, and more difficult nuclei such as natural abundance ^{13}C can typically be observed in thousands or tens of thousands of scans. Often spin-lattice relaxation times for adsorbed molecules are appreciably shorter than for the same molecules in the liquid phase. This can make the signal averaging of large numbers of scans more feasible than might have been expected.

Another family of high area solids is the zeolites,⁵ crystals with internal pores of molecular size. The interior of these pores is equivalent to a high surface area, again typically of the order of hundreds of $\text{m}^2 \text{g}^{-1}$. Whether guest molecules inhabiting these pores can be said to be adsorbed is a matter of semantic convention. In this article the NMR of such guest molecules will be only briefly touched upon.

A large number of substances can be prepared in the $10 \text{ m}^2 \text{g}^{-1}$ range, and almost any solid can be prepared with $1 \text{ m}^2 \text{g}^{-1}$. Whether a high area preparation is stable with respect to loss of area by sintering depends mainly on the temperature. Typically the temperature must be kept below about one-half of the melting point to prevent substantial loss of area. A system of great practical interest is the supported metal catalyst.⁶ These catalysts consist of metal crystallites dispersed on a refractory oxide, such as silica or alumina. This technique permits a very high dispersion of the metal, with reduced tendency to sinter, and makes the most effective use of expensive platinum group metals. While the metal dispersion is extremely high, such catalysts typically contain a few per cent of metal by mass and have metal areas of 1 to $10 \text{ m}^2 \text{g}^{-1}$ of catalyst. Monolayers of high sensitivity nuclei are straightforward even at $1 \text{ m}^2 \text{g}^{-1}$; however, if one wishes to explore nuclei of low sensitivity, or small fractions of a monolayer, severe sensitivity problems eventually arise. One possible approach to this problem is to use the Curie law enhancement of NMR sensitivity at extremely low temperatures in the millikelvin range.⁷

In general, the preparation of high-area solids will result in an aggregate of randomly oriented crystallites. Some preparations, e.g. silica gels, will lack long-range order entirely. In a few favorable cases, high-area oriented samples can be prepared, e.g. in the case of lamellar clay particles by sedimentation.⁸

If one imagines a surface prepared by the sudden cleavage of a solid, it is evident that the surface may be viewed as a macroscopic radical with large numbers of 'dangling bonds', resulting from the disruption of the chemical bonds responsible for the integrity of the solid. Such a surface will be a very reactive entity and will be subject to structural rearrangement, which can lower its free energy, and to chemical reaction with its environment. Thus all metal surfaces (with the possible exception of Au) that have been in contact with the atmosphere will be covered by a layer of oxide. This layer may be a monolayer, or may be many layers thick. Similarly, oxide surfaces that have been exposed to the atmosphere normally have a monolayer of $-\text{OH}$ groups, resulting from their reaction with H_2O . This surface OH may be regarded either as the result of chemisorption of H_2O or as a normal constituent of oxide surface.

A 'clean' surface is one whose properties approximate the idealized cleaved crystal, at least as regards chemical

composition. (Many clean surfaces undergo rearrangement of their atoms to positions different from the bulk crystal.²) Clean surfaces are of much interest in fundamental surface science studies. In general, really clean surfaces are achieved only under ultrahigh vacuum conditions on areas of the order of 1 cm^2 ; adsorption on such surfaces is inaccessible to conventional NMR study at the present time. A possible exception to this statement is scattering experiments involving polarized atomic beams,^{9,10} which can yield nuclear relaxation data and possibly other NMR-like parameters. For the most part, however, present NMR studies involve surfaces that are at best partially clean. Thus, surface oxide can be removed from the noble metals by H_2 reduction, followed by thermal desorption of the resulting adsorbed H; surface OH can be largely removed from oxide surfaces by thermal treatment under vacuum. While not too attractive from the point of view of fundamental studies, the surfaces studied by NMR can easily be kept in a state similar to those used in practical applications for adsorption and catalysis, and NMR has substantial contributions to make to these fields.

The main features of the NMR of any sample will be determined by the mobility of the molecules studied. In this context, adsorbed layers are somewhat intermediate between liquid and solid samples. For many strongly chemisorbed samples, the adsorbed species are held in place by strong chemical bonds and are solids for NMR purposes. However, strong bonding to the surface does not necessarily imply localized bonding. For example, H atoms bind to most metal surfaces with an energy in excess of 200 kJ mol^{-1} , but in the case of the platinum group metals at room temperature they are mobile parallel to the surface on the NMR timescale, and are in some sense a two-dimensional fluid. Rotational motion of adsorbed molecules is also common, but the presence of the surface is likely to introduce greater anisotropy in this motion than would be observed in a liquid. Weakly bound physisorbed molecules are typically in rapid exchange with the gas phase, and average NMR properties will be observed. For high-area solids it will usually be the case that the adsorbed population is much larger than the gas-phase population, so that properties like chemical shifts will be dominated by those of the adsorbed phase, while the rapid exchange ensures that the motional properties of the layer appear liquid-like, both translationally and rotationally.

2 EARLY RESULTS

Not surprisingly, the first NMR studies of adsorbed species involved proton NMR^{11,12}. Since these predated high resolution solid state techniques, the possible experiments were broadline studies of immobile species, 'high-resolution' studies of mobile adsorbates, relaxation/linewidth measurements, and diffusion measurements by field gradient techniques. Examples of most of these exist from before 1960. For example, O'Reilly et al.¹³ observed that surface OH on silica and silica-alumina is chemically shifted with respect to liquid H_2O , and inferred from the temperature-independent Lorentzian lineshape that the OH forms a dilute randomly populated dipolar coupled system. Hickmott and Selwood¹⁴ studied the relaxation of water and several organics on various oxides, and showed the importance of surface paramagnetic species as relaxation agents. Fuschillo and Renton¹⁵ studied

the linewidth of methane on TiO_2 at low temperatures, and demonstrated the now well-known result that submonolayer amounts of physisorbed species do not become immobile until the temperature is well below the bulk freezing point.

In spite of these early successes, surface NMR in succeeding years proved somewhat disappointing. In general, very few chemical shifts proved to be measurable because of the large linewidths found for proton resonances. The sources of these linewidths were eventually realized to be rapid relaxation, especially by surface paramagnetic species, exchange with surface protons, heterogeneity of surface with respect to adsorption energetics, and inhomogeneous broadening from the nonzero magnetic susceptibility of irregular adsorbent particles; no proton linewidths less than 1 ppm were observed and much larger linewidths were common. Given the limited range of proton shifts, little of interest was shown regarding the structure and bonding of adsorbed molecules. Furthermore, with some notable exceptions,¹⁶ it turned out to be difficult to obtain information regarding molecular motion from relaxation studies. This was largely because of the difficulties of disentangling different relaxation processes, and the often dominant effect of paramagnetic surface species, in the presence of which correlation times may be determined more by electron relaxation than by adsorbate motions. The results of this early period are well summarized in the reviews by Packer¹⁷ and Pfeifer.¹⁸ Diffusion measurements, particularly in the context of guest molecules in zeolites, have recently been reviewed by Kärger et al.¹⁹

3 MULTINUCLEAR MAGNETIC RESONANCE

More possibilities were opened by the increasing availability of multinuclear and Fourier transform NMR equipment beginning in the 1970s. If, as it turns out, lines from adsorbed species will be at least a few ppm in width, chemical shifts should be observable for nuclei whose shift range is of the order of hundreds of ppm or more. An extreme example of this is the observation²⁰ of an 80 ppm shift for Ti^{4+} adsorbed from H_2O onto silica. In a more practical vein, the early 1970s saw the first natural abundance ^{13}C spectra of molecules in zeolites²¹ and physisorbed on silica²². Linewidths were a few ppm and it was possible to observe chemical shifts due, for example, to the hydrogen-bonding interaction of adsorbed acetone with surface hydroxyls. These works also demonstrated the possibility of measuring relaxation times separately for chemically different groups within a molecule. This could lead to simpler analysis of relaxation experiments for rigid molecules and the study of internal motions for others. In the early 1980s spectra were obtained for ^{15}N in a variety of molecules in zeolites²³ and adsorbed on SiO_2 ,²⁴ showing the advantages of studying the NMR of the atom which is the site of interaction between adsorbate and adsorbent. Relaxation studies of ^{17}O in H_2O on montmorillonite and kaolinite were performed.²⁵ These showed the desirability of measuring adsorbate correlation times in a system where strong quadrupolar interaction dominates the relaxation, and yielded surprisingly short correlation times for water in these systems, on the order of 10^{-11} s . Results to 1985 on multinuclear spectroscopy and relaxation measurements on adsorbed mobile molecules are comprehensively reviewed by Nagy, Engelhardt, and Michel.²⁶

4 HIGH-RESOLUTION SOLID STATE TECHNIQUES

The advent of high-resolution solid state NMR techniques in the 1960s and 1970s opened up new possibilities for the study of adsorbate systems. The most obvious of these is the identification of immobile chemisorbed species. The first use of these techniques by Kaplan et al.²⁷ was however a CP study of physisorbed benzene and toluene at low temperatures. Observation of an axially symmetric CSA powder pattern showed that benzene undergoes rapid rotation about the hexad axis, even at 77 K. Further experiments demonstrated that rapid cooling can trap molecules in a metastable isotropically rotating state at this temperature.

Magic angle spinning was first applied to surface problems by Stejskal et al.²⁸ in their study of CO₂ in zeolites. This showed that substantial line broadening which may arise from microscopic susceptibility variations in the adsorbate can be removed by MAS. Use of MAS in surface problems suffers from the conflicting requirements of atmospheric integrity, best achieved with sealed samples, and of excellent mechanical balance, which is likely to be degraded by the sealing process. This conflict was resolved in a semisatisfactory way in 1984.²⁹

The first use of multiple pulse line narrowing in surface studies was by Schreiber and Vaughan.³⁰ This permitted the measurement of the shielding anisotropy of surface protons on SiO₂; strong dipolar coupling to ²⁷Al prevented similar measurements on Al₂O₃. The combination of multiple pulse narrowing with MAS (CRAMPS), together with the use of higher magnetic fields, has recently been leading to growing success in the proton spectroscopy of adsorbed species.

5 ADSORBATES ON METALS

The resonance of hydrogen chemisorbed on platinum was first observed by Ito et al.³¹ Subsequently, the resonance of hydrogen has been observed on Cu, W, Ru, Rh, Pd, Os, Ir, and a few alloys, by these and other workers. (In the case of W, the cleanliness of the surface is questionable.) For all of the metals, large shifts are observed which cannot reasonably be chemical shifts and must therefore be Knight shifts. For Cu the shift is to high frequency, for the others to low frequency. With Ru–Cu bimetallic clusters³² the Knight shift of H on Ru decreases steadily as the Cu content is increased.

Platinum has been the most studied of these metals and it has been established that there is little difference between metallic powders and supported Pt catalysts. It has also been found that Knight shifts are smaller when the Pt particles are very small and when the adsorbed H covers a large fraction of the metal surface. As yet these trends have not received a satisfactory quantitative explanation in terms of the bonding between H and the metal surface. For all of the above metals the linewidth of the H resonance indicates that the hydrogen is mobile at room temperature. For those which have been studied to lower temperatures, motion generally ceases before liquid nitrogen temperature is reached.

¹³C NMR of CO chemisorbed on a metal was first studied by Duncan et al. on Rh.³³ Since then it has been studied on the remaining noble metals, and on bimetallic Pt–Rh particles. Much of this work is described in the reviews by Slichter³⁴ and Duncan.³⁵ On Ru and Rh an average shift is observed that corresponds to the known shifts of metal carbonyl complexes.

In static samples a broad powder pattern is observed with an anisotropy of some 400 ppm, corresponding to a linear carbonyl. On Rh, bridging carbonyl has also been observed. At room temperature, with the highest CO loadings, a narrow line appears from CO that is rotating isotropically on the NMR timescale. Thus the NMR of CO on Rh and Ru can be interpreted in terms of chemical shifts which are completely analogous to those observed in diamagnetic metal carbonyl complexes.

On the other hand, CO on supported Pt and Pd shows large high-frequency Knight shifts. Knight shifts are not observed for CO on colloidal platinum,³⁶ but it is not clear whether this is due to loss of metallic properties in the smaller particles or to interactions with the reagents used to stabilize the colloid. Supported Os and Ir show smaller high-frequency shifts and it is hard to be certain whether these are chemical or Knight shifts. Observations on Pt–Rh clusters³⁷ show that the Knight shift disappears above about 50% Rh, even though SEDOR measurements clearly show the presence of Pt in the surface layer of the particles.

The above results indicate that one must proceed with caution in interpreting the observed line positions of chemisorbed species on metals. For example, the metal (Rh) giving the largest Knight shift for adsorbed H gives no Knight shift for adsorbed CO. Thus in the absence of a reliable and comprehensive theory for Knight shifts of adsorbed species, every adsorption system must be examined carefully on its own merits.

6 ADSORPTION PROBES OF SURFACE SITES

The nature and concentration of specific types of site on solid surfaces has long been an area of interest, especially from the point of view of catalytic activity. These features can be probed spectroscopically by observing changes in the spectrum of a small molecule upon its binding to the surface. The archetypal example is the study of acid sites on oxide surfaces by IR spectroscopy of adsorbed amines;³⁸ pyridine, for example, gives distinct lines when physisorbed, protonated by a surface Brønsted acid, or coordinated to a surface Lewis acid.

This type of probing can obviously be done by NMR, which has the advantage that quantitative accuracy is in principle better. With IR spectroscopy it is generally difficult to be confident regarding the extinction coefficient of chemisorbed species, and there are often considerable uncertainties regarding path length and adsorbate concentration. Surface acids have thus been probed by direct proton NMR and by ¹³C, ¹⁵N, and ³¹P NMR of adsorbed amines and phosphines. Such attempts have been generally successful and are complementary to IR studies. Much of the work in this area has been reviewed by Freude.³⁹

Proton NMR cannot of course detect Lewis acids directly. For quantitative assessment of differing types of acid, ³¹P spectroscopy seems the most desirable. The high sensitivity of this nucleus permits spectra to be obtained in reasonable time periods by 90° pulse excitation, avoiding the need for cross polarization which may compromise quantitative accuracy. Most results have so far been obtained with trimethylphosphine as a probe; studies of a wider range of phosphorus bases seem likely in the future.

Solid surfaces may also contain basic sites; indeed, the same surface may simultaneously contain both strong acid and strong base sites. Probing these surfaces by NMR is less well developed, but a few results are available. For example, ^{13}C spectroscopy has been used to demonstrate, through the formation of surface bicarbonate from CO_2 , the unsurprising result that surface OH on MgO is basic.

7 SURFACE HYDROXYL GROUPS

As mentioned above, all oxides are covered with a layer of $-\text{OH}$ groups, which may in a formal sense be regarded as the result of water chemisorption on an ideal oxide surface. The surface chemistry of oxides in their normal state is largely determined by the properties of these hydroxyl groups. The properties of these hydroxyl groups vary from one oxide to another, and the same oxide may show differing types of $-\text{OH}$ groups, reflecting different exposed crystal planes, or different structural arrangements. Many of the classic NMR investigations^{13,30} have dealt with these groups, and the literature of studies by IR spectroscopy is particularly voluminous. Much of the IR literature and some of the NMR investigations have been reviewed by Morrow.⁴⁰ A recent review by Mastikhin et al.⁴¹ is devoted to NMR studies, particularly of recent results obtained through magic angle spinning.

8 CHEMICAL REACTION IN ADSORBED LAYERS

Adsorbed layers are the site of heterogeneous catalysis and hence reaction in these layers is a topic of immense scientific, technical, and economic interest. NMR studies of such reactions may proceed in two rather different ways. For reasonably rapid reactions of systems that are in equilibrium under NMR conditions, the familiar methods of shift, relaxation, and lineshape analysis may be employed, as in solution NMR. The possibilities for this type of study of adsorbed systems have been reviewed by Resing.⁴² On the other hand, slow reactions may easily be studied by recording NMR spectra as a function of time. A sealed NMR tube is in many ways an ideal contamination-free reactor. Reaction studies have been greatly advanced by CP MAS techniques, which permit the potential observation of a wide range of reaction products and intermediates.

For species reacting at a convenient rate at room temperature, e.g. the reaction of trimethyl phosphite with the silica surface,⁴³ straightforward MAS spectroscopy as a function of time can provide kinetic data for the surface reaction processes. For systems that are only reactive above room temperature, a 'quick and dirty' technique is to heat samples for controlled periods of time at the reaction temperature, and then cool to room temperature for NMR observation.⁴⁴ While this method provides useful insights, it suffers from uncontrolled conditions during the heating and cooling phases, together with uncertainties about desorption.

Clearly this type of study awaits the development of reliable high-temperature sealable MAS equipment, and recent progress has been made in this direction by Haw and coworkers.⁴⁵ Unfortunately, sealed-sample MAS is always

open to uncertainties arising from the possibility of desorption when the sample is heated above its preparation temperature. There seems no obvious way of combining the traditional catalytic flow reactor with MAS NMR. For the case of static samples, an NMR-compatible flow reactor has been designed by Reimer and co-workers.⁴⁶

9 STRUCTURE OF ADSORBED SPECIES

NMR of solids has the possibility of yielding direct structural information through measurement of dipolar interactions. Since the structures of chemisorbed species are in general not readily determined, this is a powerful possibility. The fundamental problem is that the motional state of observed species is not known a priori, and it will be unclear whether an observed dipolar coupling should be corrected for motional averaging. Thus, early observations of Pake doublets from adsorbed water⁸ (see also bibliography in Pfeifer¹⁸) generally gave splittings much too small to correspond to static H_2O molecules. These results were therefore not used to infer structural information, but were instead interpreted to give motional information based on the assumption of the known structure of isolated water molecules. In a system where significant structural changes have occurred due to chemical reaction, it seems necessary to demonstrate that observed dipole couplings are independent of temperature, or to give some other evidence for lack of motion, before inferring structural parameters.

Duncan and Vaughan⁴⁷ were among the first to use modern solid state methods to determine dipolar couplings in adsorbed layers. Their H-C dipolar modulation studies of adsorbed formic acid gave essentially the same coupling as observed in crystalline formates. A deviation from the expected bond length based on X-ray measurements of calcium formate was attributed to motion, even though the couplings in the adsorbed layer appeared temperature independent.

More recently, Slichter and co-workers³⁴ have applied spin echoes and SEDOR to measure homonuclear and heteronuclear dipole couplings in adsorbed layers, and to attempt to measure the bond length between adsorbate and surface. The latter endeavor is complicated by the possibility, with heavy nuclei such as ^{195}Pt , of indirect ('scalar') couplings of magnitudes comparable to the dipolar couplings.

In principle, dipolar couplings could be estimated from relaxation or NOE measurements. In practice, the often dominant effects of surface paramagnetic impurities, and the general anisotropy of motion in adsorbed layers, render this a complicated and unattractive prospect.

A less direct way of obtaining structural information from dipolar couplings is by the observation of multiple quantum coherence, from which the size of coupled spin aggregations may be inferred. This was first applied to surface problems by Slichter and co-workers,⁴⁸ and has recently been reviewed by Hwang and Gerstein.⁴⁹

10 MOTION IN ADSORBED LAYERS

As mentioned in the previous section, structural and motional determinations are a coupled problem pair. In general

the study of motions is simpler, because for many adsorbed systems the assumption of known structures in the adsorbed layer will be chemically tenable.

As indicated above, interpretation of relaxation is difficult in adsorbed systems. More reliable motional information is likely to be obtained by the observation of approximately local molecular properties, such as chemical shift anisotropies, dipolar splittings, and quadrupolar couplings. Thus the first CP study²⁷ of an adsorbed layer revealed an axially symmetric CSA powder pattern for physisorbed benzene at 77 K. This indicated rapid rotation about the sixfold axis at a temperature well below that at which such rotation occurs in the solid.

Subsequently, Resing and co-workers used analysis of CSA powder patterns to determine the motions of various adsorbed species, such as anchored phenyl groups.⁵⁰ Sindorf and Maciel⁵¹ used cross polarization rates as an indicator of average C–H dipolar coupling to study the dynamics of long alkyl chains bound to silica surfaces. Yannoni et al.⁵² observed C–C dipolar splittings in doubly-labeled benzene to study its structure and motions on a Pt–Al₂O₃ catalyst. The use of deuterium quadrupolar powder patterns to study motions in adsorbed phases is exemplified by the elegant studies of Luz et al.⁵³ on methyl amines sorbed in zeolites.

1 INTRODUCTION

^1H NMR spectroscopy is a powerful tool for investigating acid sites on solids, especially Brønsted sites. The main advantage of ^1H NMR compared with other spectroscopies is quantitativity. High resolution ^1H NMR techniques are used to measure the chemical shift of Brønsted acid sites without interaction of a basic reagent. With adsorption of a base, this shift cannot be obtained directly because of fast exchange of the H atoms. However, this chemical exchange provides a means of measuring the acidic hydrogen chemical shift with conventional NMR techniques. Broadline NMR of ^1H in rigid lattice conditions is also used to study acidity by means of the interaction of acid sites with water, as detailed in the following discussion.

2 MEASURING THE CHEMICAL SHIFT

The ^1H chemical shift of the H atoms of SOH groups (S being the solid lattice) in solid Brønsted acids can be thought of as related to the deprotonation energy and therefore to the acidity of the O–H bonds. A quantum mechanical model of this concept has been formulated.¹

The chemical shift is a second-rank tensor characterized by an anisotropy, an asymmetry, and an isotropic value (δ_{iso}). The anisotropy of the chemical shift of ^1H in strongly homonuclear dipolar coupled solids can be measured by using appropriate multipulse sequences. The isotropic value is obtained by MAS techniques; when there are large dipolar interactions CRAMPS or isotopic dilution is used.

As moisture can seriously perturb a proton spectrum, sealed glass tubes containing pretreated samples are often used.

2.1 Isotropic Chemical Shift

2.1.1 Effect of Hydrogen Bonding

The chemical shift of SOH group H atoms depends not only on their bond polarization but also on hydrogen bond formation. Harris and Jackson² confirmed the previously

reported trends, especially in correlations between δ_{iso} and both the O ... O and the H ... O distances.

2.1.2 Dependence of δ_{iso} on Acid Strength

Pfeifer's group^{3–10} has been the most active in the use of ^1H MAS NMR of samples in sealed tubes. Working on 'anhydrous' H-zeolites (this means without template, hydration water, ammonia or any adsorbed phase, but still containing hydroxyl groups), these authors assigned the different δ_{iso} values obtained.

For Hy,³ they are (Figure 1): (a) 1.3–2.3 ppm: silanol groups, SiOH; (b) 3.8–4.4 ppm: bridging OH groups pointing towards the supercages; (c) ca. 5 ppm: bridging OH groups pointing towards the sodalite cavities; (d) 6.5–7 ppm: remaining ammonium ions; (e) 2.6–3.6 ppm: AlOH groups still bonded to the framework. They related the δ_{iso} value of signals a, b, and c to the IR frequencies of the corresponding stretching vibrations.⁶ Brunner,⁷ working at 500 MHz, showed that the proton concentrations corresponding to signals b and c are equal (Figure 1), in agreement with Freude et al.⁸ Signals a and b are common to all H-zeolites. For zeolites of different families, δ_{iso} of b increases with the Si/Al ratio⁵ for values lower than 10 and then remains approximately constant (Figure 2).

Sites with enhanced catalytic activity have been studied in mildly hydrothermally dealuminated HZSM-5 zeolite:³ this enhanced activity does not correspond to a change of δ_{iso} . The authors proposed that some of these sites are acid-insoluble tetracoordinated extraframework Al atoms. The same team identified Lewis acid sites in zeolites from the 6.5 ppm ^1H signal of H atoms of water molecules bonded to these sites.⁹

Pfeifer's team used ^1H MAS NMR for the quantitative detection of OH groups at framework defects of ZSM-5 zeolites, created during the synthesis.³ The SiOH signal, at ca. 2 ppm, represents a much greater concentration of these groups than the concentration calculated for terminal groups, in particular for ZSM-5 synthesized with TPA⁺: this template leads to a damaged lattice with a high concentration of nonintact Si–O–Si bonds after calcination.

Various combined ^1H and ^{27}Al MAS NMR studies address the hydrothermal dealumination and the realumination process of the hydrogen form of zeolites.³ Bridging OH group dehydroxylation is accompanied by the removal of the same number of aluminum atoms from the zeolite framework. After

Figure 1 ^1H MAS NMR spectrum of a completely ammonium exchanged shallow-bed activated Hy zeolite under the following experimental conditions: resonance frequency, 500 MHz; sample spinning rate, 9 kHz; pulse width, 1.6 μs ; delay time, 20 s. The asterisks denote spinning sidebands⁷

Figure 2 ^1H isotropic chemical shift of signal b of zeolites versus their Si/Al ratio. HE stands for erionite, HZ for ZSM-5, HM for mordenite⁴, and Hy for faujasite structure

realumination, the total number of bridging OH groups is approximately equal to that of the parent sample. However, it must be noticed that after a hydrothermal dealumination process all the proton spectra contain a signal characteristic of AlOH groups at ca. 3 ppm.

After adsorption of water, MAS NMR spectra recorded at room temperature cannot be used to identify and quantify the oxyhydrogenated species formed because of the superposition of several effects,⁴ in particular chemical exchange. Experiments at temperatures low enough to slow down the exchange are required for identification of individual sites.

Certain OH groups, formed by dissociation of water on divalent cations in zeolites which are known as cracking and alkylation catalysts, have also been studied.³ The bridging OH groups in MgNa-Y behave as in CaNa-Y but the OH groups associated with the metal behave differently. A line at 0 ppm, observed for MgNa-Y, is partially accessible to pyridine and attributed to MgOH. For very small amounts of water in CaNa-Y, a signal at 0.5 ppm appears and for increasing water adsorption (1–2 H₂O per cavity) a new signal at 2.8 ppm is present, the corresponding site being inaccessible to pyridine. The signal at 0.5 ppm is attributed to CaOH groups pointing to the supercages and the 2.8 ppm one to CaOH groups pointing to sodalite cavities, hydrogen bonded to framework oxygen atoms.

Rosenberger et al.¹⁰ applied the CRAMPS technique to silica gel with and without adsorption of benzene, acetone, or pyridine. Without adsorption these authors found that the OH group δ_{iso} value is spread over less than 0.5 ppm. However, adsorbed species cause δ_{iso} to change by 0–1.4, 4, or 7 ppm, respectively. Comparison of these values with those obtained with liquids suggests a $\text{p}K_{\text{a}}$ value of 10.

Dorémieux-Morin et al.¹¹, working with ^1H MAS NMR on samples out of thermodynamic equilibrium, proposed the following process for the dehydration–rehydration of amorphous silica–aluminas in vacuum:

which differs from that for zeolites:

To conclude, the above examples demonstrate clearly the interest of ^1H MAS NMR on sealed samples for determining the processes implying their acid properties. Though there is no general linear dependence between δ_{iso} and the deprotonation energy ΔE_{DP} ,¹ the relationship:

$$d(\Delta E_{\text{DP}})/d(\delta_{\text{iso}}) = -84 \pm 12 \text{ kJ ppm}^{-1} \text{ mol}^{-1} \quad (3)$$

has been proposed for catalyst surface hydroxyl groups when these groups are all bonded to cations (B, Al, Si, or P) whose first coordination sphere consists solely of oxygen atoms.¹

2.1.3 Line Narrowing by Fast Chemical Exchange

This technique can be used if MAS is not available. The interaction between SOH and a gaseous base, AH, mobilizes the OH group protons so that they give a sharp NMR signal, whereas when static they give a broad one. The heterogeneous equilibrium is:

When fast chemical exchange takes place between the protons of the different groups outlined in equation (4), the spectrum consists of a single line at $(\delta_{\text{H}})_{\text{obs}}$, resulting from the coalescence of the lines associated with the groups AH, AH_2^+ , and OH at δ_{AH} , $\delta_{\text{AH}_2^+}$, and δ_{OH} , respectively. The line is then narrow enough for the chemical shift to be measured on a spectrometer appropriate for liquid state NMR:

$$(\delta_{\text{H}})_{\text{obs}} = p_{\text{OH}}(\delta_{\text{H}})_{\text{OH}} + p_{\text{AH}}(\delta_{\text{H}})_{\text{AH}} + (p_{\text{AH}_2^+})(\delta_{\text{H}})_{\text{AH}_2^+} \quad (5)$$

where p_i is the molecular fraction of group i . Due to the number of parameters in equation (5) the dissociation coefficient, α , of $\text{SO}^- \text{H}$ is needed before δ_{iso} can be determined. This is possible when the absorbed phase AH contains at least one nucleus other than ^1H which can be detected by NMR, for example ^{15}N or ^{17}O .

The case of ammonia adsorbed on silica xerogel pretreated at 10^{-2} Pa at different temperatures has been detailed.¹² Nitrogen-15 NMR gives:

$$(\delta_{\text{N}})_{\text{obs}} = p_{\text{NH}_3}(\delta_{\text{N}})_{\text{NH}_3} + (p_{\text{NH}_4^+})(\delta_{\text{N}})_{\text{NH}_4^+} \quad (6)$$

from which $p_{\text{NH}_4^+}$ and α are determined. Bonardet et al. calculated $\delta_{\text{iso}} = 2$ ppm for silica xerogel; they found 4–5 ppm for silica–alumina.¹² These values are in agreement with results obtained under conditions of MAS.

2.2 Anisotropic Chemical Shift

A chemical shift anisotropy of 5.5 ppm has been measured by Ernst¹³ for silica OH groups. For zeolite bridging OH groups, the measured values are 19 ± 2 ppm; SAPO-5 exhibits a smaller value, 14.5 ± 2 ppm.¹⁴

3 RESULTS FROM THE SIMULATION OF BROADLINE SPECTRA RECORDED UNDER RIGID LATTICE CONDITIONS

There are two reasons why the proton is a convenient nucleus for investigating catalysts using broadline NMR: (a) its spin is $\frac{1}{2}$; (b) the range of its chemical shifts is small enough to be negligible compared with the main effect which is the dipolar interaction between spins. When this effect is studied two important points must be borne in mind: (i) the experimental temperature must be low enough to prevent diffusional and rotational motion of molecules or groups of atoms within the sample; this is the so-called 'rigid-lattice condition'; (ii) the interaction between two spins distance r apart is proportional to r^{-3} ;¹⁵ consequently, closest neighbor spins will give the greatest effect.

The interaction of water (as a base) with Brønsted acidic sites is proposed as:

From the standpoint of broadline NMR, each of the chemical species in equation (7) is a magnetic configuration of protons, characterized by their number and the geometry of this configuration. The interaction between neighboring protons belonging to distinct configurations is approximated by Gaussian broadening of the spectra of each configuration. The parameter of the Gaussian for each configuration is related to the shortest distances between protons of distinct configurations. The spectrum of each chemical species in powder samples is calculated by using the following magnetic configurations: (i) H_2O : the two-spin configuration calculated by Pake;¹⁵ (ii) $\text{H}_2\text{O} \cdots \text{HOS}$: the three-spin isosceles configuration revised by Dorémieux-Morin;¹⁶ (iii) H_3O^+ the three-spin equilateral configuration revised by Richards and Smith,¹⁷ or the three-spin isosceles configuration, if the ion is assumed to be deformed (all three spin configurations were first calculated by Andrew et al.); (iv) SOH: either a Gaussian and/or a Lorentzian curve for the SOH groups considered together, or a much broadened two-spin configuration.

The species H_2O and H_3O^+ (assumed to be undeformed) are characterized by a single intraconfiguration H H distance parameter (r); two are required to characterize $\text{H}_2\text{O} \cdots \text{HO}$ and distorted H_3O^+ (r and r' , the value r in the base being the shorter). The concentrations of the oxygen-protonated species known from the weights of the corresponding contributions to the fitted spectrum are normalized to the total number of H atoms in the sample. Furthermore, since the number of independent parameters for each simulation is high, it is assumed that no initial SOH group can be condensed to water molecules and that no adsorbed water molecule gives SOH groups.

The spectra are generally recorded at 4 K as the derivative of the absorption relative to the static magnetic field, using a 'homemade' probe matched and tuned at the experimental temperature.

Studies of two catalysts are described. In the second, H zeolites, the result of a synergy between Brønsted and Lewis acid sites is shown. Together with these results on catalysts, those obtained on other solids allow a Brønsted scale of acidity to be proposed.

3.1 Study of the Superficial Constitutive Water of Titania

The spectra of the superficial constitutive water of large specific surface area titanium oxides (rutile,¹⁸ anatase,¹⁹ and an amorphous sample²⁰) have been recorded at -130°C for dehydration in vacuum at various temperatures.

At each step of dehydration, simulation gives the nature and the relative concentration of the various species (SOH and $\text{H}_2\text{O} \cdots \text{HOS}$ in this case) and the approximate shortest H–H distances between these species.

For rutile and anatase, the numerical results are compared with the proton distribution which can compensate the electrostatic imbalance created by the lattice breaking, i.e. the existence of the surface. Considering the weight and distance parameters, the authors selected the high atomic density planes for which the change in the hydration remained compatible with the NMR spectra. They deduced that the most probable surface planes are (110) for rutile and (001) for anatase. In the most hydrated samples, OH groups cover the surface completely. Half the OH groups are hydrogen bonded to water molecules. Preexisting water molecules and some formed by condensation of OH groups are eliminated as soon as dehydration is performed at a temperature higher than 20°C .

In the most hydrated sample of the amorphous oxide each OH group is hydrogen bonded to a water molecule and, taken together, they cover the whole surface which means that water molecules probably form several hydrogen bonds to the surface.

3.2 Acidity of Zeolites

Batamack et al.^{21,22} studied, in HY-zeolite, the equilibria described in equation (7). The 'anhydrous' samples were first obtained by shallow-bed treatment at 400°C . The concentrations of the oxygen-protonated species were measured for different amounts of readsorbed water which gains access to all acid sites. Comparison with results obtained by ^1H MAS NMR indicated that the samples were cooled to 4 K quickly enough for these concentrations to be equal to those at room temperature. A nondealuminated HY sample,²¹ denoted ND, and a partially dealuminated HY sample obtained by $(\text{NH}_4)_2\text{SiF}_6$ exchange in aqueous solution,²² denoted D, were studied.

The main results were the following:

(1) No interaction was found between silanol groups and water molecules, which is in agreement with results from ^1H MAS NMR.

(2) For ND HY:²¹ (i) The first step of interaction between ZOH groups (ZOH denotes the bridging Brønsted sites) and water molecules may be described by equation (8) (where x and y are numerical values): the hydrogen-bonded species concentration is limited by the smallest of the initial concentrations of ZOH or H_2O ,

where $\inf(x, y)$ means the smallest value of x or y . (ii) An equilibrium is established between the hydrogen-bonded species and the ionized ones,

Figure 3 Plot of hydronium concentration in Y-zeolite per Brønsted acid site, $\text{H}_3\text{O}^+/\text{as}$, versus the adsorbed water molecule concentration per Brønsted acid site, $\text{H}_2\text{O}/\text{as}$; ■, ND HY;²¹ △, D HY²²

From Figure 3, the hydronium concentration per Brønsted acid site, $\text{H}_3\text{O}^+/\text{as}$, remains constant when the adsorbed water concentration, $\text{H}_2\text{O}/\text{as}$, is larger than 1, in agreement with the value calculated from equations (8) and (9).

(3) For D HY,²² on the contrary, $\text{H}_3\text{O}^+/\text{as}$ increases strongly when $\text{H}_2\text{O}/\text{as}$ is larger than two. The authors proposed that a synergy between Brønsted and Lewis acid sites explains this difference (the Lewis sites are identified, using ^1H MAS NMR, by the molecular water that they bond).²³

The conclusion is that broadband ^1H NMR provides a means of quantitatively determining the Brønsted acidity obtained by the interaction of water with the acid sites of the H-zeolites, whatever the nature of these sites. ^1H MAS NMR and other physicochemical techniques can help to identify these sites.

3.3 Scale of Brønsted Acidity in Solids

Using broadband ^1H NMR, Batmack et al.²⁴ compared for different solids the results obtained when the number of water molecules is equal to the number of OH groups being tested.

First, hydronium ion concentrations can be compared (Table 1). The ionization coefficient for ND HY-zeolite, $\text{H}_3\text{O}^+/\text{as}$,

Figure 4 Half experimental absorption derivative curve for $\text{H}_2\text{Sb}_4\text{O}_{11} \cdot 2\text{H}_2\text{O}$,; fitted spectrum, —; weighted contribution of H_3O^+ ions, —; weighted contribution of $\text{H}_2\text{O} \cdots \text{HO}$ groups, - - -.

is 0.2 (see Section 3.2). For dihydrated antimononic acid, $\text{H}_2\text{Sb}_4\text{O}_{11} \cdot 2\text{H}_2\text{O}$, this coefficient attains a value of 0.4. In these cases simulations required two distinct magnetic configurations (Figure 4). For Nafion, the sensitivity is low but the ionization coefficient has been found to be about 1.

Since zeolite silanol OH groups are not observed to interact with water molecules, they are considered not to be acidic. No hydronium ions were found for amorphous titanium oxide nor for dihydrated dihydrogeno-aluminum tripolyphosphate. Hence, basing an acidity scale on the ionization coefficient gives only limited results: zeolite ($\text{SiOH} \cdot \text{H}_2\text{O}$) $\approx$ $\text{TiOH} \cdot \text{H}_2\text{O} \approx \text{H}_2\text{AlP}_3\text{O}_{10} \cdot 2\text{H}_2\text{O} < \text{HY-zeolite SiOH(Al)} \cdot \text{H}_2\text{O} < \text{H}_2\text{Sb}_4\text{O}_{11} \cdot 2\text{H}_2\text{O} < \text{Nafion}$.

However, broadband ^1H NMR improves the classification of the samples relative to their acid strength by comparing the hydrogen-bonded complexes that their SOH groups form with water molecules. The values of r and r' allow a description of the hydrogen bond strength in terms of the O O distance, assuming C_{2v} symmetry for the $\text{H}_2\text{O} \cdots \text{HOS}$ group (Table 1).

For amorphous titanium oxide the O O distance is ca. 285 pm: the hydrogen bonds are weak. Only one three-spin magnetic configuration was required for a good simulation of $\text{H}_2\text{AlP}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$ (Figure 5), showing that the H atoms are really at the apices of an isosceles triangle. A very short O O distance, 242 pm was obtained: the hydrogen bonds are relatively strong. The O O distances are found to be about 259 pm and 247 pm in the zeolite and the antimononic acid, respectively. Ordering the samples versus the strength of the

Table 1 Acidity Scale Using Broadband ^1H NMR : The Condition is that Samples Contain One Water Molecule Per OH Group being Tested²⁴

Order of increasing Brønsted acid strength	Sample	Number of H_3O^+ per initial OH: ionization coefficient	Number of $\text{H}_2\text{O} \cdots \text{HO}$ per initial OH	O O distance (pm) in $\text{H}_2\text{O} \cdots \text{HO}$ (assumed C_{2v}) from r and r'
1	Zeolite silanols	0	0	
2	Superficial OH groups on amorphous TiO_2	0	1	285
3	$\text{H}_2\text{AlP}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$	0	1	242
4	Zeolite SiO(H)Al	0.2	0.8	259
5	$\text{H}_2\text{Sb}_4\text{O}_{11} \cdot 2\text{H}_2\text{O}$	0.4	0.6	247
6	Nafion	1	0	

Figure 5 Half experimental absorption derivative curves for $\text{H}_2\text{AlP}_3\text{O}_{10}\cdot 2\text{H}_2\text{O}$, and +++++; fitted spectrum which is the weighted contribution of $\text{H}_2\text{O} \cdots \text{HO}$ groups, ———²⁴

hydrogen bonds gives: zeolite $\text{SiOH}\cdot\text{H}_2\text{O} < \text{TiOH}\cdot\text{H}_2\text{O}$ on amorphous titanium oxide $< \text{HY-zeolite SiOH(Al)}\cdot\text{H}_2\text{O} < \text{H}_2\text{Sb}_4\text{O}_{11}\cdot 2\text{H}_2\text{O} \leq \text{H}_2\text{AlP}_3\text{O}_{10}\cdot 2\text{H}_2\text{O}$.

By analogy with the usual expression for acidity in aqueous media, the ionization coefficient is regarded as the principal criterion of acid strength. When the classification obtained differs from that based on the hydrogen bond length, the ionization coefficient order will be adopted. However, the strength of the hydrogen bonds can be used when no ionization occurs. The results are summarized in Table 1, the complete order of the samples being: zeolite $\text{SiOH}\cdot\text{H}_2\text{O} < \text{TiOH}\cdot\text{H}_2\text{O}$ on amorphous titanium oxide $< \text{H}_2\text{AlP}_3\text{O}_{10}\cdot 2\text{H}_2\text{O} < \text{HY-zeolite SiOH(Al)}\cdot\text{H}_2\text{O} < \text{H}_2\text{Sb}_4\text{O}_{11}\cdot 2\text{H}_2\text{O} < \text{Nafion}$.

4 CONCLUSIONS

The interest of ^1H MAS NMR for determining the properties of solid acids and the processes implying their acid characteristics is evident. However, using δ_{iso} of the SOH group as a measure of acidity is limited to samples where the first coordination sphere of the cation (B, Al, Si, or P) consists solely of oxygen atoms. When ^1H MAS NMR at low temperature becomes routine, it will be possible to measure the interaction between SOH groups and an external base of convenient strength and hardness, chemical exchange being then frozen. It must, however, be remembered that δ_{iso} can be measured under conditions of fast chemical exchange by applying conventional NMR techniques to two nuclei of the sample, ^1H and another.

When molecular water is the base, rigid lattice ^1H broadline NMR with simulation of the spectra is, at the moment, the only tool for analyzing the distribution of protons between the oxygen-protonated species formed, useful also in the case of synergy between Lewis and Brønsted acidity. Most of the spectra can be simulated with three kinds of magnetic configuration: (i) two spins, (ii) three spins at the corners of

an equilateral triangle, and (iii) three spins at the corners of an isosceles triangle, plus Gaussian and/or Lorentzian curves.

A scale of Brønsted acidity of solids can be deduced from rigid lattice ^1H broadline NMR experiments performed when the number of water molecules is equal to the number of Brønsted sites. The ionization coefficient and the strength of the hydrogen-bonded species formed are used to set up this acidity scale.

1 INTRODUCTION

Chemical exchange, i.e. the transfer of atoms, molecules or molecular groups between two or more different environments or regions, is a phenomenon encountered frequently in studies by NMR of a wide variety of chemical, physical and biological systems. Different environments are usually revealed in NMR experiments through distinct resonance frequencies, spin–spin coupling constants, or relaxation times characteristic of the regions between which chemical exchange takes place. The types of atomic or molecular motion most often investigated on metal surfaces include surface diffusion, adsorption and desorption, exchange between different surface sites or different types of adsorbed species, molecular reorientation, and reorientation of molecular groups.

Because NMR requires at least ca. 10^{18} spins at the surface to be able to detect a signal, single crystal surfaces cannot be studied (10^{15} spins). However, introducing the metal in the form of small particles with diameters in the order of nanometers into porous materials, provides a sufficiently high number of surface sites for adsorption to be studied by NMR. These support materials are mostly oxide compounds like silica, alumina, titania, or zeolites with high internal surfaces of several hundred square meters. At the same time, highly dispersed supported metals, e.g. group VIII elements like ruthenium, rhodium, palladium, osmium, iridium, and platinum, are very often of interest in basic and applied research in catalysis (see also *Supported Metal Catalysts*, and *Adsorbed Species: Spectroscopy and Dynamics*).

Several NMR techniques are available to study exchange phenomena of adsorbed species. Spin–lattice relaxation¹ measurements are useful if chemical exchange dominates as a source for relaxation, or can be separated from other relaxation mechanisms, e.g. relaxation via the conduction electrons of the metal, called Korringa relaxation (see *Electron–Nuclear Hyperfine Interactions*). To be investigated by relaxation measurements, the characteristic time constants of exchange τ_{ex} have to be in the order of 10^{-9} s for spin–lattice relaxation in the laboratory frame to 10^{-5} s for spin–lattice relaxation in the rotating frame.¹ For a review of the relaxation method used to study the dynamics on surfaces we refer the reader to the literature.^{2–4} The analysis of lineshapes or resonance shifts

obtained by conventional NMR techniques are sensitive in the dynamic range of $10^{-6} \leq \tau_{\text{ex}} \leq 10^{-3}$ s. Spin labeling methods extend this range up to more than 10^{-1} s. Two-dimensional NMR techniques, applicable in approximately the same slow dynamic range, are most effective if the exchanging species exhibit separate NMR peaks or if well-defined lineshapes due to anisotropic interactions can be observed.⁵

In the present article the theoretical basis necessary to understand the evolution of nuclear spin magnetization influenced by chemical exchange is outlined briefly. The reader is introduced to spin-labeling and two-dimensional (2D) NMR techniques, which are frequently used to monitor exchange. Finally, experimental examples regarding chemical exchange on metal surfaces are discussed.

2 THEORY OF MAGNETIZATION EXCHANGE

In the following it is assumed that the spatial motion of molecules or atoms can be described classically. If all spin interactions are secular with respect to the Zeeman interaction, i.e., the corresponding interaction Hamiltonians commute with the Zeeman Hamiltonian, then each spin can be considered as being subjected to a local field arising from the environment, superimposed on the external static field. Chemical exchange has the effect of causing random fluctuations of the local field. For example, a nuclear spin situated in a molecule or atom, which jumps randomly between two regions on a surface, such that each region gives rise to a different isotropic resonance shift, experiences a random modulation of its resonance frequency. The influence of such frequency fluctuations upon the NMR lineshape was first treated by Hahn, Maxwell, Gutowsky, McCall, and Slichter.⁶

If the spin Hamiltonian contains nonsecular terms, arising, for example, from J couplings observed commonly in liquids, a quantum-mechanical treatment (spin density matrix formalism) is required.⁷ Splittings due to J couplings are often difficult to detect in NMR studies of adsorbates on metal surfaces because of insufficient spectral resolution, caused by the heterogeneity of the system, leading to distributions of isotropic chemical or Knight shifts, and/or the presence of ‘solid-like’ spin interactions much stronger than J coupling, like chemical shift anisotropy (see *Internal Spin Interactions and Rotations in Solids*) and paramagnetic shifts.

We confine ourselves here exclusively to the case of secular spin interactions, leading to a classical probabilistic model for the magnetization exchange originating from chemical exchange processes. The probabilistic model is commonly represented by a stationary Markov process,^{8,9} allowing the derivation of equations of motion for the nuclear spin magnetization in the form of generalized Bloch equations.^{9–11} The evolution of longitudinal and transversal magnetization components for all regions, between which exchange takes place, are given as a system of coupled differential equations with rate coefficients describing the magnetization exchange process. Solving these equations is a standard problem of analysis and matrix algebra (see Ernst et al.¹¹ and Jeener et al.¹³) and enables explicit calculation of NMR lineshapes.

Figure 1 illustrates the principal effects on the NMR lineshapes originating from magnetization exchange between two regions or sites. Regions A and B, populated by N_A and N_B spins, respectively, are characterized by distinct resonance

Figure 1 (a) NMR lineshape versus $\delta\omega\tau_{\text{ex}}$ for symmetric two-site exchange ($N_A = N_B$). (b) Variation of the resonance frequency in the fast exchange limit as a function of $N_A:N_B$

frequencies ω_A and ω_B , $\delta\omega = \omega_B - \omega_A$. This difference of resonance frequencies may be caused by different isotropic chemical or Knight shifts. In the slow exchange limit, $\delta\omega\tau_{\text{ex}} \gg 1$, where τ_{ex} is a characteristic time constant for the exchange process, two separate lines appear in the NMR spectrum [Figure 1(a)], which become broadened with decreasing $\delta\omega\tau_{\text{ex}}$, and coalesce to a single broad line at $\delta\omega\tau_{\text{ex}} \approx 1$. With $\delta\omega\tau_{\text{ex}}$ decreasing further, only one single ‘exchange-averaged’ narrow line is observed (fast exchange limit, $\delta\omega\tau_{\text{ex}} \ll 1$). The spectra in Figure 1(b) were calculated for the fast exchange limit varying the ratio $N_A:N_B$ of spin numbers in regions A and B, leading to a variation in the resonance frequency of the exchange averaged resonance line as well as to a broadening for values of $N_A:N_B$ near unity. The dependence of the resonance shift δ on N_A and N_B can be expressed for the fast exchange limit as the weighted average:

$$\delta = \frac{N_A}{N_A + N_B} \delta_A + \frac{N_B}{N_A + N_B} \delta_B \quad (1)$$

of the individual resonance shifts δ_A and δ_B . The mathematical formalism to calculate the above lineshapes is still applicable if anisotropic interactions, to be described by interaction tensors, e.g. chemical shift anisotropy, are present. However, because of the random spatial orientations of the principal tensor axes in a powder sample, the resulting orientation dependence of the resonance frequencies has to be taken into account to obtain the lineshape.¹⁰

3 ADVANCED NMR TECHNIQUES TO MONITOR EXCHANGE

As shown above, no significant changes of the one-dimensional NMR lineshapes or frequencies occur in the slow exchange limit. More advanced NMR techniques are available to detect such slow exchange processes.

3.1 Spin Labeling by Selective Excitation

The idea of spin labeling is based on the fact that the actual chemical exchange process, being in thermal equilibrium, causes an exchange of spin magnetization.¹² The latter is initially prepared by irradiation of rf pulses to be in nonequilibrium. The irradiation of an rf pulse, or a sequence of rf pulses affects only spins resonating within the spectral excitation window defined by the Fourier transform of the pulse sequence [Figure 2(a) and (b)]. Although this Fourier picture is only an approximation when selective saturation or inversion is considered,¹² it is a useful qualitative description. Denoting the length of a single rf pulse or the total duration of a pulse sequence by τ_p , the excitation width in the frequency domain is proportional to $1/\tau_p$, with the rf carrier frequency in the center of the excitation window. The irradiation of either a long pulse of low rf power or a sequence of strong, but very short pulses, as indicated in Figure 2(a), allows selective excitation of spins. The pulse sequence can be adjusted to act in total like a 90° pulse (selective saturation) or a 180° pulse [selective inversion, illustrated in Figure 2(c)]. Therefore, spins within the spectral window can be labeled, for example, by inversion of their magnetization, while spins which resonate outside the window remain unaffected. If a pulse sequence is used, excitation sidebands also occur [Figure 2(b)]. During a subsequent time interval τ_m [Figure 2(a)] the spin system is allowed to undergo free time evolution. The NMR signal is detected finally by a short (nonselective) 90° pulse. Selective excitation (saturation or inversion) of a narrow frequency band within a broad NMR line, for example, caused by chemical shift anisotropy, is called ‘spectral hole-burning’. If chemical exchange is present, the labeled spins may change their resonance frequencies resulting in a redistribution of spin

Figure 2 Spin labeling by selective excitation: (a) pulse sequence, (b) Fourier transformation of the train of equidistant pulses, and (c) NMR spectrum showing a selectively inverted line

magnetization toward spectral regions outside of the selected window. The recovery of the spectral hole, or of the intensity of an inverted single resonance line, can be measured as a function of the recovery time τ_m to reveal the kinetics of a chemical exchange process.

Magnetization recovery is also caused by spin–lattice relaxation of the spin magnetization. Only exchange processes with a characteristic time τ_{ex} shorter than the spin–lattice relaxation time T_1 can be observed. Spin-labeling becomes ineffective if the chemical exchange process is faster than the spin-labeling process itself (characteristic time constant τ_p). Thus accessible by spin-labeling techniques are exchange processes within a timescale $\tau_p < \tau_{ex} < T_1$.

3.2 Two-Dimensional Exchange NMR

Two-dimensional exchange NMR techniques¹³ are based on the idea of measuring the frequency of spin magnetization components at two different times during the NMR experiment. After the initial preparation period, which consists of a waiting period to allow equilibration of the longitudinal magnetization and irradiating the first $\pi/2$ pulse, transversal magnetizations are present, oscillating with frequencies ω_A and ω_B during the time t_1 [evolution period, Figure 3(a)] corresponding to spins located in regions A and B. A second $\pi/2$ pulse converts the magnetization present at time t_1 into longitudinal magnetization. During the mixing time τ_m (usually much longer than the time t_1) slow chemical exchange leads to a random modulation of the precession frequencies of the two magnetization components M_{zA} and M_{zB} . Spins which were resonating at ω_A at the end of the period t_1 may resonate at either ω_A or ω_B at the end of the mixing period τ_m (and vice versa). The NMR signal is detected after the final $\pi/2$ pulse during the time period t_2 . Repeating the experiment by incrementing the time t_1 in small steps, yields a two-dimensional time-domain interferogram which after 2D Fourier transformation¹¹ with respect to t_1 and t_2 gives the 2D NMR spectrum $S(\omega_1, \omega_2)$. If exchange occurs between A and B, cross peaks are observed, labeled A $\rightarrow$ B and B $\rightarrow$ A in Figure 3(b), in addition to main peaks A and B located along the principal diagonal.¹⁴

4 CHEMICAL EXCHANGE OF ADSORBED SPECIES ON METAL SURFACES: EXAMPLES

Chemical exchange phenomena at or near metal surfaces observed by NMR encompass a wide dynamical range extending from the fast exchange limit ($\tau_{ex} < 10^{-5}$ s) to extremely slow processes ($\tau_{ex} > 1$ s). The details of the chemical exchange processes might be quite different, originating, for example, from adsorption or desorption, exchange between different surface sites, exchange between different populations of adsorbed species or surface diffusion.¹⁵

4.1 Exchange Dynamics of CO Adsorbed on Metals

Carbon-13 spin labeling techniques have been applied by Duncan, et al.¹⁶ to elucidate in detail surface diffusion of

Figure 3 (a) Basic 2D NMR pulse sequence to monitor exchange. (b) Schematic representation of a 2D NMR spectrum for exchange between two sites A and B

CO and slow exchange between different carbonyl species adsorbed on rhodium. Molitor and Apple¹⁷ performed ^{13}C NMR powder lineshape calculations for reorientating dicarbonyl groups bonded to rhodium. Surface diffusion of CO chemisorbed on palladium has been investigated by means of ^{13}C relaxation measurements and lineshape analysis.¹⁸

4.2 Fast Exchange of Hydrogen on Metal Surfaces

Proton NMR peaks of hydrogen interacting with metal surfaces are commonly shifted to lower frequency (i.e. upfield) due to the Knight shift interaction and reveal relatively small linewidths, especially at elevated external H_2 pressures and temperatures above room temperature, indicating high intrinsic mobility. Variations of the resonance frequency of ^1H NMR peaks, attributed to hydrogen on the metal surface, versus pressure (i.e. changing the number of hydrogen atoms or molecules on the surface) may be caused by at least two different mechanisms: (i) fast exchange between surface environments with different Knight shifts [as illustrated in Figure 1(b)]; and (ii) by a variation of the Knight shift interaction itself, because the latter may be a function of the surface coverage. As pointed out above, fast exchange between two regions leads to an averaged NMR line representing hydrogen in both regions. Variation of the resonance shift

Figure 4 ^1H NMR resonance shift δ for hydrogen adsorbed on ruthenium–copper bimetallic particles and fraction X_{Ru} of surface ruthenium as a function of the copper content

with pressure, or coverage, has been observed quite frequently by ^1H NMR¹⁹ or ^2H NMR²⁰ for hydrogen adsorbed on various metals like platinum, rhodium, and ruthenium (see also refs. 18–20 and 23–24 given in Wu et al.¹⁹). The resonance shift variation of hydrogen due to fast exchange between different surfaced regions has been used to monitor the surface composition of bimetallic particles.²¹ In this case hydrogen atoms are rapidly exchanging between sites on the bimetallic particle surface, composed of sites with different Knight shifts for adsorbed hydrogen. As shown in Figure 4, on particles consisting of pure ruthenium, hydrogen resonates at -62 ppm [to low frequency relative to tetramethylsilane (TMS)]. Increasing the total copper content of the sample leads to a systematic decrease of the ^1H NMR resonance shift δ , approaching asymptotically the value of -49 ppm for a copper content near 80 at%. This shift value is regarded as the resonance shift for hydrogen adsorbed on copper sites of ruthenium–copper bimetallic particles. Applying equation (1) inserting $\delta_{Cu} = -49$ ppm and $\delta_{Ru} = -62$ ppm, the fraction $X_{Ru} = N_{Ru}/(N_{Ru} + N_{Cu})$ of ruthenium atoms exposed at the particle surface can be determined (see Figure 4). Therefore, in this example the ^1H NMR resonance shift provides a sensitive measure for the composition of the surface.

4.3 Slow Exchange Between Different Hydrogen Populations on the Metal Surface

Figure 5(a) shows an in situ ^1H NMR spectrum of silica supported ruthenium, obtained at $T = 400$ K and at an external H_2 pressure of 300 Torr.²² Two distinct resonance lines (denoted as α and β) are observed, originating from two different hydrogen species, characterized by different heats of adsorption. The 2D exchange NMR spectrum [Figure 5(b)] was obtained by the pulse sequence illustrated in Figure 3(a). The cross peaks reveal a slow exchange process within the timescale of the experiment, given by the mixing time $\tau_{\text{mix}} = 2$ ms, occurring between α and β hydrogen, but there is no exchange within this timescale between the α or β species and the hydrogen residing on the silica support. Spin

Figure 5 (a) Conventional ^1H NMR spectrum of silica supported ruthenium. (b) 2D exchange NMR spectrum at $T = 400$ K and external H_2 pressure $p = 300$ Torr

labeling of one of the two spin species, α or β , by selective excitation (Figure 2) allows the determination of the average time constant, $\tau_{\text{ex}} = 700 \mu\text{s}$, for the magnetization exchange between α and β hydrogen.

1 INTRODUCTION

The advances in NMR over the last three decades have resulted in an increasingly important role that this technique has played in studies of various types of carbonaceous materials. Among these materials are fossil fuels which, due to their impact as a main world energy source, are of primary concern in scientific and engineering research. Of great interest are naturally occurring raw materials, such as coal, crude oil, and oil shales, as well as products of fossil fuel processing. The latter include 'coke', a term used to describe a solid by-product of the petroleum refining process, or a hard, often porous residue left after the destructive distillation (pyrolysis) or liquefaction of coal.

Fossil fuels are known to be enormously heterogeneous and complex materials and no single approach can provide adequate understanding of their structure and best way of utilization. Although the classical chemical methods and some modern analytical techniques (e.g. mass spectroscopy, liquid and gas chromatography, thermogravimetry) have proved useful in characterizing parent materials as well as liquid and gaseous products of coals and petroleum processing, determination of the chemical and physical structure of solid fossil fuels and solid products of fuels processing has not been possible by employing these methods. This need has stimulated application of other spectroscopic techniques including X-ray spectroscopies (X-ray atomic fluorescence and X-ray photoelectron spectroscopy), infrared spectroscopy, optical spectroscopies (laser spark spectroscopy, Raman spectroscopy), ESR spectroscopy, and NMR spectroscopy, which soon came to the forefront of this research. Earlier NMR studies utilized primarily relaxation studies, quantitative analysis of ^1H in solids using wideline NMR, and provided quantitative and structural analysis of fossil fuel derived liquids (mainly from coal and petroleum) via liquid state NMR. Since the implementation of high-resolution methods of ^1H decoupling, magic angle spinning and CRAMPS, and the methods of enhancing polarization of rare nuclear spins (cross polarization and dynamic nuclear polarization) it became possible to acquire high-resolution spectra of ^1H and ^{13}C in a short measuring time.¹

In spite of different origins, petroleum and coal derived cokes consist primarily of carbon (typically ca. 90% by weight)

and hydrogen (below 5%). While smaller concentrations of oxygen, sulfur, nitrogen and various metals (vanadium, nickel, iron) are also present in cokes, it is not surprising that NMR spectroscopy utilizes ^1H and ^{13}C nuclei to probe these materials. Below, an overview is given of the fundamental aspects of solid state NMR of ^1H and ^{13}C as applied to the studies of carbonaceous solids. The topics include relaxation studies, quantitation, high-resolution methods in ^{13}C and ^1H NMR, lineshape analysis, and the relationship between NMR derived data and the chemical structure. Although the utilization of solid state NMR techniques will be shown largely for petroleum derived cokes, most of the approaches described here are also pertinent to fossil fuels, semi-cokes, coal tar pitches, petroleum pitches and other 'bottom-of-the-barrel residues' (see also *Coal Structure from Solid State NMR and Fossil Fuels*), as well as for characterization of carbonaceous residues (cokes) from catalyst-controlled reactions.

2 RELAXATION PARAMETERS OF HYDROGEN AND CARBON IN COKES

Measurements of nuclear spin relaxation in solid fossil fuels have been performed in order to provide gross information about local environments and molecular motions, long before modern high-resolution solid state NMR techniques were introduced as an analytical tool. Three relaxation times were commonly measured: (a) T_1 , the longitudinal relaxation time characterizing attainment of equilibrium of spin magnetization along a static magnetic field, and generally associated with dipolar fields fluctuating at the Larmor frequency, generated by motion of other magnetically active nuclei and/or unpaired electron spins associated with free radicals; (b) $T_{1\rho}$, the longitudinal relaxation time in the rotating frame characterizing similar motions in the tens of kilohertz frequency range; and (c) T_2 , the transverse relaxation time characterizing static spin interactions in solids.

Most of the spin-lattice relaxation studies reported for cokes employed ^1H NMR and showed that T_1^{H} and $T_{1\rho}^{\text{H}}$ relaxation processes (typical values in the 50–200 ms and 0.3–5 ms range, respectively) depend upon interactions between protons and unpaired electrons (via spin diffusion), while dipolar interactions between protons have a lesser significance. To limit the number of parameters, only a biexponential function is usually used to fit the experimental data although no physical model that justifies such procedure has yet been established. Also, due to the presence of different relaxation mechanisms, and different types of paramagnetic species, a distribution of relaxation parameters is very likely. In such cases the relaxation parameters are the result of a complicated interplay between competing relaxation mechanisms, and spin diffusion may not be effective to identify structural inhomogeneities, even if they existed in cokes. For example, the detailed study of 15 petroleum cokes, produced from pure and mixed residues of various origins, showed that the T_1^{H} and $T_{1\rho}^{\text{H}}$ relaxation parameters (including relative fractions of magnetization exhibiting fast and slow relaxation) could not be directly correlated with different structural parameters of cokes as determined by high-resolution methods.² In particular, these results did not reveal structural inhomogeneities in cokes in which

aliphatic and aromatic structures dominate. In spite of difficulties with the interpretation of spin lattice processes in cokes, the accurate analysis of T_1^H and $T_{1\rho}^H$ is often required to characterize quantitatively the cokes via ^{13}C CP MAS experiments.

The proton T_2 relaxation time (or the NMR linewidth), determined under a single pulse excitation, reflects the strength of static ^1H – ^1H dipolar interactions in cokes, and in the absence of molecular motion is a measure of the average internuclear distance in a sample. Unlike coals, which generally exhibit at least two exponential decays, the pyrolyzed cokes show typically a Gaussian decay of transverse magnetization with a single value of T_2 of roughly $20\ \mu\text{s}$, indicating homogeneously rigid character of the coke structure, where only hindered motions of functional groups (e.g. CH_3) take place.² When molecular motion characterized by correlation time $\tau_c < 10^{-5}\text{ s}$ is present, e.g. in coals with mobile molecular fragments, solvent swollen coals, pitches above their softening point or during pyrolysis, the increased values of T_2 are a measure of molecular mobility. The measurements of T_2 versus temperature allowed the study, for example, of the glass transition temperature in materials resulting from pyrolysis of petroleum pitches and coal extracts through the mesophase stage to a coke.³

3 QUANTITATION OF HYDROGEN AND CARBON

One of the main reasons NMR has become a powerful analytical tool is because for spin- $\frac{1}{2}$ nuclei, such as are ^1H and ^{13}C , the NMR signal may generally be used for quantitative analysis. Using NMR for hydrogen (or carbon) spin counting in cokes implies that: (1) all spins are observed by NMR, (2) the initial (near $t = 0$) time dependence of the FID is known and can be compared with that of a standard, and (3) the physical meaning of all components of the FID is well understood. In single pulse experiments the first few microseconds of the FID are always obscured by the probe ringdown and receiver deadtime, which may result in considerable signal loss in samples with short T_2 . This short time behavior of the NMR signal can be determined, and the lost intensity recovered, by using a solid echo excitation sequence, or by applying linear prediction techniques directly to the FID.²

Hydrogen is the most sensitive nucleus commonly detected by NMR, but it is also one of the least sensitive when analyzed by chemical methods. In general, NMR offers quick and most reliable measurements of hydrogen concentration in fossil fuel materials, which compare favorably with the results of combustion analysis, Karl–Fisher titration and other techniques. The main possible source of systematic loss of the NMR signal (typically below 10%) is the broadening of the NMR line from dipolar interactions with unpaired electrons present in organic free radicals in cokes. As already mentioned, the analysis of the FID also provides information about molecular mobility.

The quantitative analysis of carbon by single pulse NMR is time consuming due to long ^{13}C relaxation times T_1^C and is considered less accurate than chemical analyses. It is mainly used to address the potential quantitation problems in the CP MAS spectra.

4 NMR LINESHAPES IN COKES

The dominant line broadening interactions that affect the NMR lineshapes are chemical shift anisotropy and ^1H – ^1H and/or ^1H – ^{13}C dipolar couplings. However, even if these interactions are eliminated, or reduced, by the high-resolution techniques, the observation of sharp resonances in ^1H and ^{13}C NMR is often precluded by the heterogeneous chemical nature of cokes. The results of high-resolution ^1H and ^{13}C NMR when combined with spin counting, elemental analysis, and other analytical methods, can be used to infer several structural parameters and the ‘average’ model of a coke.

4.1 ^1H CRAMPS NMR

With values of transverse relaxation times T_2 around $20\ \mu\text{s}$, proton linewidths in cokes are ca. 30 kHz, corresponding to 100 ppm at a resonance frequency of 300 MHz. This line broadening results from high abundance and large magnetic moment of ^1H spins, and exceeds the range of proton chemical shifts in hydrocarbons, which is about 15 ppm. Consequently, no information concerning chemical environment of hydrogen can be derived from the NMR spectrum, unless the ^1H – ^1H dipolar interactions are overcome by a suitable NMR technique. However a combination of MAS and homonuclear dipolar decoupling via a multiple pulse sequence (WAHUHA, MREV or BR-24) allows the achievement of quantitative ^1H NMR spectra with linewidths of less than 0.3 ppm in favorable cases [Figure 1(a)]. This technique is referred to as CRAMPS (combined rotation and multiple pulse spectroscopy) (see **CRAMPS**).⁴

In general, CRAMPS spectra of cokes are less resolved than the spectra of pure crystalline hydrocarbons and some coals; nevertheless, two absorption bands can usually be distinguished, centered at ca. 7 ppm and ca. 2 ppm, and associated with aromatic CH protons, and protons attached to sp^3 carbon atoms, respectively (Figure 1).^{2,5} The linewidths corresponding to the two maxima are typically 3–5 ppm [full width at half maximum height (FWHM)], with the inhomogeneous broadening mainly attributed to distribution of chemical shifts. The use of the MREV-8 sequence seems satisfactory for CRAMPS spectroscopy of fossil fuels, as the application of more sophisticated pulse sequences like BR-24 does not lead to increased resolution in these materials. Due to substantial overlap of the aromatic and aliphatic peaks, the spectra are deconvoluted for quantitative analysis by using a superposition of Gaussian lines. The usefulness of the CRAMPS technique becomes apparent when differences in the spectra are viewed as a function of coking conditions, e.g. time or temperature of pyrolysis.⁶

4.2 ^{13}C NMR Techniques: CP MAS and Bloch Decay

^{13}C NMR spectra of cokes, coals and coal-derived products can be measured using conventional single pulse excitation (Bloch decay experiment), or by ^1H – ^{13}C cross polarization, which, combined with high-power ^1H decoupling and MAS, yield spectra with well resolved aromatic and aliphatic carbon bands (Figure 2). Typically, the low-frequency (aliphatic) part of the spectrum consists of a peak located between 10 and

Figure 1 ^1H CRAMPS spectra of (a) citric acid, 187 MHz; (b) Pittsburgh No. 8 Argonne Premium Coal, 300 MHz; and (c) petroleum coke produced at Mobil from heavy crude oil, 300 MHz. [Spectrum (a) reproduced by permission of Academic Press from G. E. Maciel, C.E. Bronnimann, and B.L. Hawkins, in 'Advances in Magnetic Resonance: The Waugh Symposium', ed. W.S. Warren, 1990, Vol. 14, p. 125. Spectrum (c) reproduced by permission of Pergamon Press from M. Pruski, D. Michel, and B. C. Gerstein, *Carbon*, 1994, **32**, 31]

50 ppm with features that can be assigned to methyl and methylene carbons. The aromatic peak, centered at ca. 130 ppm, is associated mainly with C–H perimeter and nonprotonated aromatic carbons. Although ^1H decoupling and MAS substantially reduce the large broadening due to ^1H – ^{13}C dipolar interaction (ca. 20 kHz) and chemical shift anisotropy (ca. 200 ppm), the ^{13}C spectra of coals and cokes cannot match the liquid-like resolution achieved for many crystalline organic compounds (Figure 2). Again, NMR reflects the chemical complexity of these materials, because the resonances originating from a distribution of chemical environments are superimposed in the spectra.

A variety of sources can limit the accuracy of the intensities measured in these experiments which raised serious concern about the quantitative reliability of ^{13}C NMR methods in the analysis of carbonaceous solids.⁷ Several factors that define resolution and quantitative information are general for ^{13}C NMR spectroscopy, e.g. interference of molecular motions with MAS and ^1H decoupling, incomplete recovery of carbon magnetization in Bloch decay experiments due to very long

Figure 2 25 MHz ^{13}C CP MAS spectra of (a) sucrose, (b) German brown coal, and (c) petroleum coke produced from heavy crude oil ($t_{\text{CP}} = 1$ ms, spinning speed $\nu_r = 4.5$ kHz)

T_1^{C} relaxation times, and signal loss due to broadening from paramagnetic centers (cokes contain typically ca. 10^{19} unpaired electrons per gram).

Additional difficulties arise when cross polarization is used to enhance the carbon signal.^{7–10} The time evolution of carbon magnetization during the CP MAS experiment is a result of a complicated interplay between the spin–lattice relaxation processes in the rotating frame and the cross-polarization processes (described by relaxation time $T_{1\rho}^{\text{H}}$ and the time constant for cross-polarization process, T_{CH}), which, in turn, are further influenced by sample spinning and sample heterogeneity (see *Cross Polarization in Rotating Solids: Spin-1/2 Nuclei*). In the simplest case, the time dependence of the ^{13}C magnetization $M_c(t_{\text{CP}})$ during the cross polarization contact is given by:

$$M(t_{\text{CP}}) = M_0 \lambda^{-1} \left[1 - \exp \left(-\lambda \frac{t_{\text{CP}}}{T_{\text{CH}}} \right) \right] \times \exp \left(-\frac{t_{\text{CP}}}{T_{1\rho}^{\text{H}}} \right) \quad (1)$$

where M_0 is the carbon equilibrium magnetization, t_{CP} is the cross polarization contact time, and $\lambda = 1 - (T_{\text{CH}}/T_{1\rho}^{\text{H}})$.¹¹ For quantitative measurements it is required that the build-up of carbon magnetization, determined by T_{CH} , is completed before the loss of proton polarization occurs due to $T_{1\rho}^{\text{H}}$ relaxation (i.e. hydrogen having short $T_{1\rho}^{\text{H}}$ values are not contributing to cross polarization, leaving a substantial fraction of carbons ‘undetected’, unless $T_{\text{CH}} \ll T_{1\rho}^{\text{H}}$). In general, a wide distribution of T_{CH} times exists in cokes due to different ^{13}C – ^1H distances and internal motion. MAS introduces additional time dependencies to homo- and heteronuclear dipolar Hamiltonians and further complicates the polarization transfer. Since, as described earlier, the $T_{1\rho}^{\text{H}}$ relaxation processes are also complex in cokes, with substantial fractions of spins having $T_{1\rho}^{\text{H}}$ values of 500 μs or less,² the condition $T_{\text{CH}} \ll T_{1\rho}^{\text{H}}$ may not be satisfied for those ^{13}C nuclei that are far from the nearest proton, e.g. those that are deeply incorporated in polycondensed aromatic rings.

In spite of the unfavorable cross-polarization dynamics, CP MAS experiments are being successfully applied in the studies of fossil fuels. Most researchers have conceded that, when carefully performed, CP MAS experiments provide quite accurate ^{13}C lineshapes, which in most cases agree well with those obtained from Bloch decay experiments. This assertion seems particularly pertinent for cokes, which by nature are more homogeneous than coals, and a too low carbon spin count in the CP MAS spectra does not necessarily imply an incorrect analysis of carbon functionality. In addition, several CP MAS-based spectral editing techniques have been proposed and applied to carbonaceous solids. The dipolar dephasing experiment has been traditionally used for discriminating between different carbons based on the strength of their dipolar interactions with protons.¹² In coals and cokes, this technique allowed discrimination between aromatic tertiary and aromatic quaternary ring carbons, as well as between aliphatic quaternary and CH_3 carbon atoms and combined CH and CH_2 .^{12,13} The recently proposed CP MAS sequences that combine depolarization and polarization inversion allow the generation of subspectra representing each of four CH_n ($n = 0, 1, 2, 3$) subsystems (see *Spectral Editing Techniques: Hydrocarbon Solids*).¹⁴

The following experimental conditions and procedures are recommended for obtaining the most reliable CP MAS spectra of solid fossil fuels.^{7,9,10}

1. The longitudinal relaxation times $T_{1\text{H}}$ and $T_{1\rho}^{\text{H}}$ should be carefully measured using ^1H NMR.
2. Measuring of ^{13}C intensities with variable cross-polarization contact times in the 10 μs to 30 ms range, and fitting the data to equation (1) to obtain the total magnetization $M_{\text{c}}(0)$. Often two components of T_{CH} and $T_{1\rho}^{\text{H}}$ are necessary to produce a good fit.
3. The use of low MAS frequency (<5 kHz) is useful to avoid the interference of sample spinning with the cross-polarization process. Consequently, the measurements should be performed at low static magnetic fields (<2.5 T) to avoid the spinning sidebands in the spectra and the necessity of spinning sideband suppression. Since the dominant line broadening mechanisms in the CP MAS

spectra are heterogeneous, resolution is almost independent on the magnetic field strength.

4. Accurate adjustment of the Hartmann–Hahn match, especially when MAS frequencies of >5 kHz are used.

Finally, the last few years have seen the development of a variety of CP MAS based experiments designed in order to enable efficient cross polarization and evade some of the quantitative distortions in ^{13}C NMR spectra. These techniques include stop-and-go spinning (STAG),¹⁵ magic angle hopping¹⁶ (see *Magic Angle Turning and Hopping*) and amplitude-modulated cross polarization schemes (AMCP).¹⁷

While the CP MAS technique is applied in most studies, the Bloch decay experiment has recently become a feasible alternative. With the advent of large MAS rotors, spinning of several cubic centimeters of sample is now possible at 4 kHz, and a reasonable signal-to-noise (S/N) ratio can be achieved in ^{13}C MAS spectra of cokes within a few hours of measuring time, even if the recycle delay of several minutes is required between successive transients.¹⁸ The Bloch decay spectra represent >90% of carbon in many cokes, with the only loss of signal attributed to paramagnetic broadening, and the method is preferable for quantitative studies. As the MAS capabilities continue to improve, Bloch decay may become increasingly used in the future research, leaving CP MAS measurements for quick qualitative surveys, comparative studies, measurements of C–H interactions and spectral editing.

4.3 Other NMR Techniques

The rotating frame dynamic nuclear polarization cross polarization experiment (rf DNP-CP)¹⁹ is an alternative ^1H – ^{13}C polarization scheme which allows nuclear polarization to be enhanced by irradiating the free electrons in a sample. The DNP technique is particularly well suited for solid fossil fuels and substantial carbon signal enhancements have been reported for coals.¹⁹ The DNP experiment requires, however, a source of microwave power and some modifications of the NMR spectrometer (see *Dynamic Nuclear Polarization and High-Resolution NMR of Solids*).

Variable angle sample spinning (VASS) is another method which partly averages the chemical shift anisotropy while allowing measurements of CSA lineshapes and CSA tensor values (see *Variable Angle Sample Spinning*). The technique has proved useful in supplementing other types of NMR data to estimate the structure of polycondensed aromatic materials such as some coals and chars.⁹

Also, high temperature in situ NMR has recently embraced fossil fuels and related materials.²⁰ Several NMR studies were reported in which thermally induced changes in molecular dynamics and chemical shift information during pyrolytic decomposition and formation of solid carbonaceous residues, including coking processes, have been monitored at temperatures as high as 800 K. For these materials, which could be studied above their softening point (e.g. hard coal tar pitch and mesophase pitch prepared from decant oil), ^1H and ^{13}C NMR provided highly resolved signals (<1 ppm) that allowed for identification of various structural units.²¹

5 STRUCTURAL PARAMETERS OF COKES

The primary implication of solid state NMR studies of cokes is an enhanced understanding of their chemical

composition. Although the structural information obtained from solid state NMR studies is less detailed than that provided for the feedstocks using liquid state NMR techniques,²² the parameters measured by ^1H and ^{13}C NMR can be used to estimate the 'average' models of these materials.^{2,8} The parameters include: hydrogen and carbon concentrations (from quantitative NMR analysis); hydrogen and carbon aromaticities, as obtained from high-resolution NMR of ^1H and ^{13}C ; fraction of aromatic carbon atoms with directly bonded protons (from ^{13}C NMR with dipolar dephasing); the total H/C mole ratio; and the mole fractions H/C (aromatic) and H/C (aliphatic). Due to their heterogeneity, the validity of 'average' models to describe coals has been questioned by some researchers. However, it is often useful to describe these materials in terms of average properties, as the identification of all individual constituents is very difficult, if not impossible, to accomplish. Also, NMR and elemental analysis show that cokes are more chemically homogeneous, and have low concentrations of heteroatoms, which facilitates structural determination. Two examples of basic structural types present in cokes produced from heavy crude oils by delayed coking at ca. 700 K are shown in Figure 3.² These materials may be viewed as high molecular weight conglomerates of polycyclic aromatic, hydrogen deficient structures, formed by covalent bonds or methylene bridges. The structures shown in Figure 3 are typical of cokes, although carbon aromaticities close to 100% were observed for materials produced under more severe coking conditions. Similar structural parameters were also measured for coal liquefaction residues, coal tar pitches, and residual carbons (coke) from thermal decomposition of oil shales.²³ In the last study, a CP MAS technique was used to monitor the decrease of aliphatic carbon peak intensity and formation of polycondensed quaternary carbon at higher temperatures.

For a variety of fossil fuels, solid state NMR spectra can be combined with characterization of feedstocks by liquid state NMR, MRI and high temperature in situ NMR to provide unique identification of structural changes during the entire coking, pyrolysis or liquefaction processes. Such studies

allow monitoring of the loss of organic aliphatic matter, while cracking, polymerization and aromatization reactions progress during pyrolysis and the precursors of coke are formed. Following the progress of these reactions has notably improved the understanding of the chemistry of carbonization, and allowed optimization of the technology used in the coking process.

1 INTRODUCTION

Porous media are of considerable interest in a very diverse range of activities. Porous media comprise a wide variety of substances—plastics, ceramics, cements, clays, rocks, porous glasses, carbons, silica gels, and zeolites. Even biological tissues may share many features of porous media. Depending on the given nature, the pore diameters in these substances may range from the subnanometer region up to macroscopic dimensions. The efficiency of their technical use is intimately connected with their transport properties. Diffusion measurements in porous systems are therefore of direct practical relevance. Moreover, systematic diffusion studies in such systems may contribute to a better understanding of such fundamental questions as the interaction between molecules and solid surfaces,^{1–3} and the behavior of molecular systems of reduced dimensionality.⁴

Among the methods of studying molecular diffusion in porous media, NMR spectroscopy is of particular relevance. As a noninvasive method, it allows the observation of molecular transportation without interfering with the internal processes. The technique may be applied under both equilibrium and nonequilibrium conditions. Using different NMR techniques, various aspects of molecular transport may be investigated, including the elementary processes of diffusion and the rate of molecular propagation over microscopic and macroscopic distances. A review of the principles of these techniques and examples of their application is given in Section 2. Probably the most powerful NMR method for studying molecular propagation is the pulsed field gradient method (PFG-NMR), and this is described in more detail in Section 3. The capability of PFG-NMR to trace indications of anomalous diffusion in porous media is discussed in Section 4. Finally, as an illustration of the versatility of PFG-NMR, Section 5 summarizes the information provided by this method about molecular diffusion in beds of microporous crystallites (zeolites).

2 PIECES OF INFORMATION

The most straightforward way of applying NMR to study diffusion in porous media is based on the fact that the intensity of an NMR signal is directly related to the

number of the observed nuclei. Using this correlation it was possible to measure the rate of molecular exchange between zeolite crystallites of type ZSM-5⁵ and NaX,⁶ loaded with ordinary (i.e. hydrogen containing) benzene and the surrounding atmosphere of deuterated benzene. The intracrystalline diffusivities estimated on the basis of the measured exchange rates were in excellent agreement with the data determined directly by PFG-NMR in the identical sample and verified the equivalency of macroscopically and microscopically measured diffusivities.

The information provided by the NMR signal intensity is significantly enhanced when the measurements are performed under the influence of well defined inhomogeneities of the magnetic field. Under such conditions, the resonance frequency becomes space dependent, so that the NMR spectrum may be directly correlated with the distribution of the nuclei under consideration within the sample. This method has become popular under the names 'NMR tomography' or 'NMR spin mapping', due to its spectacular progress in application to anatomical imaging in medicine⁷ (cf. articles on biomedical applications in this Encyclopedia). However, its application is certainly not confined to biomedicine; in particular, a wide variety of NMR imaging studies have been concerned with molecular propagation in porous media.^{8,9} A summary of the most recent results may be found in the proceedings of the 'International Meeting on Recent Advances in NMR Applications to Porous Media', Bologna, 1990,¹⁰ and Canterbury, 1993.¹¹

An interesting possibility of tracing mass transfer in porous systems is provided by ¹²⁹Xe NMR.¹² For this purpose, the system under study is brought into contact with a xenon atmosphere. Since, besides the pore architecture and the chemical composition of the pore surface, the chemical shift of ¹²⁹Xe NMR also depends on the nature and the concentration of the molecules in the interior of the porous system, the ¹²⁹Xe NMR spectrum reflects the distribution function of molecular concentrations within the sample. If there are, for example, two regions of different concentration of the molecular species under study, the ¹²⁹Xe NMR spectrum should consist of two different lines. Obviously, the merging rate of the two lines is directly correlated with the rate of equilibration of the internal concentration, and provides direct information about the intrinsic diffusivities. This measuring principle has been used to study molecular transportation in both the micropores¹³ and the macropores^{14,15} in zeolitic adsorbate–adsorbent systems.

In the methods so far mentioned, we have exclusively considered samples that are not at equilibrium, either in the strict macroscopic sense, or at least with respect to the different isotopes involved. As soon as equilibrium is attained, these methods cannot provide any information about molecular diffusion. It is one of the great advantages of NMR spectroscopy to be able to follow even the molecules themselves on their individual diffusion paths. The information thus obtained may concern the elementary steps of diffusion as well as the rate of molecular propagation over much larger distances. Information about the elementary steps of diffusion of molecules under the influence of the internal system of porous media may be deduced from an analysis of the nuclear magnetic relaxation times and the NMR spectra.

Proton magnetic relaxation studies offer the advantage that most molecules of interest in diffusion studies of porous media

contain hydrogen atoms, and that, except for the non-naturally-occurring tritium, the magnetogyric ratio, and hence the signal-to-noise ratio, is largest for the hydrogen nucleus.¹⁶ Proton magnetic relaxation of molecules in contact with solid surfaces is mainly determined by magnetic dipole interaction with protons of the same molecule (intramolecular proton–proton interaction), with protons of other molecules (intermolecular proton–proton interaction), and with paramagnetic ions. The different contributions may be separated by a ‘relaxation analysis’.¹⁷ Except for extremely pure substances, longitudinal relaxation is controlled by the magnetic dipole interaction with paramagnetic ions. If the longitudinal electron spin relaxation time of these paramagnetic ions is much greater than the mean residence time between subsequent diffusion jumps, then proton magnetic relaxation is affected by the translational motion of the molecules with respect to the ions, and the temperature dependence of the longitudinal relaxation time is found to pass a distinct minimum, which is characterized by the condition that at this temperature the mean residence time is of the order of the reciprocal of the resonance frequency.¹⁷

The problem of separating the various contributions to nuclear magnetic relaxation can be overcome to a certain degree by studying the deuteron magnetic resonance. This is due to the almost completely dominant interaction energy of the electric quadrupolar moment of the deuteron with the intramolecular electric field gradient at the nuclear site in comparison with the various magnetic coupling energies. Since the deuteron magnetic resonance frequency depends on the orientation of this electric field gradient with respect to the external magnetic field, molecular reorientations with time constants of the order of the reciprocal of the linewidths will lead to characteristic changes in the NMR spectra, including a narrowing of the total spectrum.^{18,19} The thus-estimated reorientation times for several hydrocarbons in X-type zeolites were found to be in excellent agreement with the directly measured diffusivity, if one assumes that the molecular mean jump lengths are of the order of the distance between neighboring supercages.²⁰

In an identical manner, molecular reorientation also leads to a narrowing of NMR lines in the case of chemical shift anisotropy. Measurements of this type have been carried out with various nuclei (¹³C and ³¹P), and numerical simulations have been developed to allow the measured spectra to be attributed to the corresponding reorientation times in the relevant geometry.^{21,22}

Since the confinement of the molecules to the internal surface of porous media often leads to a preferential orientation of the molecules, the orientation correlation function will generally not decay to zero by mere local reorientation. Rather, the complete decay to zero necessitates molecular migration to positions with changed orientational preference. This process of ‘reorientation mediated by translational displacements’ (RMTD)²³ may be traced by measuring the longitudinal nuclear magnetic relaxation times in the range of low resonance frequencies (in particular by the field cycling technique²⁴), corresponding to the large correlation times of this process. Tracing RMTD has been shown to be an informative tool for studying both molecular dynamics and structural properties in micrometer and submicrometer length scales of porous systems.^{23,25}

In more open porous structures, overall nuclear magnetic relaxation is significantly influenced by the rate of exchange

between the region of intense relaxation (the magnetization ‘sinks’) and the bulk phase. The theoretical analysis of this situation^{26,27} shows that the relaxation pattern is controlled by the relationship between the mean diffusion time over a characteristic length scale of the individual pores (e.g. their radius) and the overall relaxation time to be expected under the condition of fast exchange. For diffusion times exceeding the (hypothetical) overall relaxation time, the observed relaxation behavior depends notably on the exchange conditions, yielding information about both the pore sizes and the intrinsic diffusivities.^{26–28}

At the beginning of this section ¹²⁹Xe NMR was introduced as a tool for following the evolution of molecular concentration profiles within porous media. This technique clearly includes the observation of the distribution of the xenon atoms themselves. In microporous materials where the individual cavities are separated by narrow ‘windows’, the population distribution of the xenon atoms within the individual cavities may be determined.²⁹ In addition to this local structural information, by using a second time dimension in the NMR experiments (two-dimensional exchange NMR), one may even determine the rate of molecular exchange between cavities of different occupation numbers. This method has been successfully applied to the study of intracrystalline diffusion of xenon in NaA-type zeolites.³⁰

Common to all the methods so far considered is the fact that the information about molecular self-diffusion is based on the applicability of certain models. There is, however, the possibility of monitoring directly the probability distribution of molecular propagation. This possibility is provided by transient NMR measurements in a magnetic field with well-defined inhomogeneities of large intensity. The most important representative of these techniques, PFG-NMR, is described in more detail in the rest of this article.

3 PRINCIPLES OF PFG-NMR

The principles of diffusion measurement by NMR may be easily visualized by using the classical concept of nuclear magnetism. According to this concept, any individual spin will carry out a precessional motion about the direction of the constant magnetic field with a precessional frequency given by the Larmor relationship:

$$\omega = -\gamma B \quad (1)$$

where γ is the magnetogyric ratio. In PFG-NMR, the constant magnetic field is superimposed over two short time intervals δ by an inhomogeneous field

$$B_{\text{add}}(\mathbf{r}) = \mathbf{g} \cdot \mathbf{r} \quad (2)$$

the so-called ‘field gradient pulses’. According to equation (1) these pulses have the effect that the positions of the individual spins at the instants of the field gradient pulses are recorded by the precessional phases

$$\phi(\mathbf{r}) = \int \omega dt = -\gamma(B + \mathbf{g} \cdot \mathbf{r})\delta \quad (3)$$

accumulated during these time intervals. The two field gradient pulses are generally incorporated into the classical $\pi/2-\tau-\pi$ rf pulse sequence which gives rise to a transient NMR signal (the ‘spin echo’) at time 2τ after the initial $\pi/2$ pulse. Being proportional to the total magnetization, the intensity of the spin echo depends on the dephasing of the precessional phases of the individual spins at time 2τ . Since the dephasing effected by the first field gradient pulse according to equation (3) is inverted by the π pulse, for immobile spins it is exactly compensated by the second field gradient pulse which is applied after the π pulse. However, if the individual molecules (and with them the spins) have moved during the time interval between the field gradient pulses, the refocusing will be incomplete and the intensity of the transverse magnetization will not be fully restored to its original value. NMR signal attenuation must therefore be expected to increase with increasing displacements during the ‘observation time’ (i.e. the time interval between the two field gradient pulses), and with increasing width δ and amplitude g of the field gradient pulses.

For a quantitative analysis we consider a particular spin which has been at positions $\mathbf{r}_1$ and $\mathbf{r}_2$ during the first and second field gradient pulses, respectively. According to equation (3), the phase shift of such a spin in comparison with a spin fixed in space is equal to $\gamma\delta\mathbf{g}\cdot(\mathbf{r}_2 - \mathbf{r}_1)$. The total magnetization is the vector sum of the dipolar moments of the individual spins. Thus, in complex notation, the vector sum of the transverse nuclear magnetic moments of all spins involved yields

$$\Psi = \int \int \exp[i\gamma\delta\mathbf{g}\cdot(\mathbf{r}_2 - \mathbf{r}_1)] p(\mathbf{r}_1) P(\mathbf{r}_2, \mathbf{r}_1, \Delta) d\mathbf{r}_1 d\mathbf{r}_2 \quad (4)$$

where Ψ denotes the ratio between the NMR signal intensity observed with and without magnetic field gradient pulses, $p(\mathbf{r}_1)$ denotes the probability (density) of finding a spin at position $\mathbf{r}_1$ (i.e. during the first magnetic field gradient pulse), and $P(\mathbf{r}_2, \mathbf{r}_1, \Delta)$ denotes the probability (density) that a spin which has been at position $\mathbf{r}_1$ during the first field gradient pulse will have come to $\mathbf{r}_2$ after a time interval Δ (i.e. during the second field gradient pulse). As it contains the complete information about the process of molecular propagation, the function $P(\mathbf{r}_2, \mathbf{r}_1, \Delta)$ has been termed the ‘propagator’. (This expression must clearly not be confused with the operator $\hat{U}(t)$ which is generally termed in the same way and describes the evolution of the ensemble of the magnetically resonant nuclei under study.) Integrating over all possible starting positions $\mathbf{r}_1$, one may introduce a mean propagator³¹

$$P(\mathbf{r}, \Delta) = \int p(\mathbf{r}_1) P(\mathbf{r}_1 + \mathbf{r}, \mathbf{r}_1, \Delta) d\mathbf{r}_1 \quad (5)$$

which denotes the probability that during time Δ an arbitrarily selected molecule within the sample will be displaced over $\mathbf{r}$. With this notation, equation (4) becomes

$$\Psi = \int \exp[i\gamma\delta\mathbf{g}\cdot\mathbf{r}] P(\mathbf{r}, \Delta) d\mathbf{r} \quad (6)$$

Since equations (4) and (6) formally coincide with the expressions for the intermediate incoherent scattering function in

neutron scattering, PFG-NMR has been repeatedly interpreted as a scattering experiment^{32–35} with a generalized scattering vector

$$\mathbf{k} = \gamma\delta\mathbf{g} \quad (7)$$

The maximum value of this quantity is of the order of 10^7 m^{-1} , yielding a lower limit of about 100 nm for the space scale covered in PFG-NMR experiments. The much larger scattering vectors in neutron scattering experiments confine diffusion measurements by this technique to maximum displacements of the order of only a few nanometers. Hence, for the observation of molecular transportation phenomena on the micrometer scale, PFG-NMR represents a unique method.

PFG-NMR has been successfully applied to the study of molecular diffusion in a wide spectrum of substances, including pure liquids and gases, polymers, liquid crystals, membranes, biological tissues, as well as the vast group of porous media. Detailed introductions to the experimental procedure with special emphasis on the various techniques which may be applied to enhance the sensitivity of this method and to circumvent the omnipresent pitfalls in experimental work may be found in the literature.^{33–39} In most cases, molecular diffusion, as observed by PFG-NMR, is considered to follow the laws of ordinary diffusion. The validity of this assumption is considered in the next section.

4 ORDINARY VS ANOMALOUS DIFFUSION

The total molecular displacement of any molecule during the observation time Δ of a PFG-NMR experiment may be understood as the result of the displacements of this molecule during the different time intervals into which the observation time Δ may be subdivided. Under the assumption that subsequent displacements are independent of each other and are controlled by the same probability distribution then, according to the central limit theorem of statistics for a sufficiently large number of time intervals, the distribution of the sum of these displacements will be given by a Gaussian function with a mean square distribution being proportional to the number of time intervals considered and, hence, to the observation time. Since this probability distribution is in fact the propagator, in the case of three-dimensional diffusion, for example, we may thus write

$$P(\mathbf{r}, \Delta) = (4\pi D\Delta)^{-3/2} \exp(-r^2/4D\Delta) \quad (8)$$

where the self-diffusion coefficient D has been introduced via the required proportionality between the mean square displacement and the observation time:

$$\langle r^2(\Delta) \rangle = 6D\Delta \quad (9)$$

Molecular random walk following equation (8) [and hence equation (9)] is called ‘ordinary diffusion’. It is completely described by the self-diffusion coefficient D . The definition of the self-diffusion coefficient by the Einstein relationship [equation (9)] is equivalent to that by Fick’s first law:⁴⁰

$$\mathbf{j}^* = -D \nabla c^* \quad (10)$$

where the self-diffusion coefficient is introduced as the factor of proportionality between the negative concentration gradient and the flux density of labeled molecules at macroscopic equilibrium. Inserting equation (8) into equation (6), one obtains for the signal attenuation in PFG-NMR for ordinary diffusion:

$$\Psi = \exp(-\gamma^2 \delta^2 g^2 D \Delta) \quad (11)$$

With equation (9), signal attenuation may also be expressed as a function of the mean square displacement:

$$\Psi = \exp(-\gamma^2 \delta^2 g^2 \langle r^2 \rangle / 6) \quad (12)$$

In deriving equation (4) [and hence equations (11) and (12)] it has implicitly been assumed that the molecular displacements during the field gradient pulses are much smaller than those in the interval between the two gradient pulses (narrow-pulse limit).³³ Only under this assumption can the NMR signal attenuation be related to the propagator in such a straightforward way. In the case of ordinary diffusion, the finite field gradient pulse width may be exactly taken into account by replacing Δ by an ‘effective’ observation time $\Delta - \delta/3$.

Any violation of the conditions for the applicability of the central limit theorem must be expected to lead to deviations from ordinary diffusion. Very often, in particular considering molecular diffusion in fractal networks, in the case of ‘anomalous’ diffusion the mean square displacement should obey a simple scaling law

$$\langle r^2(t) \rangle \propto t^\kappa \quad (13)$$

where now, in contrast to ordinary diffusion, the time exponent κ is smaller than 1. It may be shown⁴⁰ that the fractal dimension of the trajectory of a random walker obeying equation (13) is equal to $2/\kappa$. As a simple inversion of the central limit theorem, one may conclude that in the case of anomalous diffusion subsequent displacements must be correlated. Analytical expressions for this correlation may be deduced from equation (13).⁴¹ By using these expressions it can be shown that in the narrow-pulse approximation for anomalous diffusion the PFG-NMR spin echo attenuation is also given by equation (12). For finite pulse widths δ , the expression for the spin echo attenuation is more complicated⁴¹ and cannot be deduced from the narrow-pulse approximation by simply introducing an effective observation time.

The search for indications of anomalous diffusion is a current topic of PFG-NMR. Recent progress in the sensitivity towards smaller molecular displacements, in particular including the possibilities of the stray-field modification of the steady-gradient spin echo NMR method,⁴² did in fact allow the observation of anomalous diffusion in polymer melts and solutions.^{34,43,44} Scaling laws with time exponents κ differing in the range 0.25–0.5 could be confirmed, partially by varying the observation time over orders of magnitude. No similar breakthrough in detecting indications of anomalous diffusion in porous media has yet been achieved. As an example, Figure 1 shows the mean square displacement of *n*-hexadecane adsorbed on active carbon as a function of the observation time.⁴⁵ Over two orders of magnitude the observed time dependence is in complete agreement with that of ordinary diffusion,

Figure 1 Mean square displacement of *n*-hexadecane adsorbed on active carbon at a pore filling factor of 0.43 versus observation time Δ at: (○) 291 K, (□) 323 K, (△) 363 K, and (◇) 413 K. The straight line indicates the dependence⁴⁵ $\langle r^2(\Delta) \rangle \propto \Delta$

although the internal pore system can be described by introducing fractal dimensions. One should note, however, that in the measurements there was only a very small overlap between the pore distribution function and the minimum displacements observable by PFG-NMR.

Molecular transportation in porous crystallites over distances sufficiently exceeding the dimensions of the elementary units clearly fulfils the conditions for the application of the central limit theorem. It is not surprising, therefore, that PFG-NMR measurement of intracrystalline diffusion in zeolites has not thus shown any deviation from ordinary diffusion. There is, however, an intriguing exceptional case, where even in zeolites molecular transportation must be expected to deviate from ordinary diffusion. Such a situation may occur when the zeolite pore system consists of parallel channels, as for example in zeolites ZSM-12 or $\text{AlPO}_4\text{-5}$. As soon as the channel diameters are so small that the molecules cannot pass each other, by theoretical considerations⁴⁶ the molecular mean square displacement may be shown to be proportional to the square root of the observation time rather than to the observation time itself. The experimental verification of this phenomenon of ‘single-file’ diffusion⁴⁷ is a task for PFG-NMR.

In the following final section, by reviewing selected PFG-NMR studies on zeolites, typical examples are given of the application of this NMR technique to diffusion measurements in porous systems. The variety of attainable information will demonstrate that the confinement to ordinary diffusion in these

substances in no way diminishes the attractiveness of such investigations.

5 DIFFUSION IN MICROPOROUS CRYSTALLITES (ZEOLITES)

According to the original definition, zeolites are microporous crystalline aluminosilicates. In the last few years, dramatic progress in zeolite synthesis has made possible the production of a large number of zeolite structure types with the aluminum and/or silicon atoms replaced by other components such as phosphorus, gallium, germanium, boron, and beryllium. Moreover, with these new structural components, a number of new structure types have been realized which have no equivalent among the aluminosilicates.⁴⁸ It has become common use, therefore, to apply the term 'zeolites' quite generally to microporous crystalline solids. The diameters of the zeolite crystallites are typically in the micrometer range. Therefore, molecular propagation within beds of zeolite crystallites proceeds both within the individual crystallites (in the 'micropores') and in the intercrystalline space (the macropores or

transport pores). In the case of gas phase adsorption, which we shall consider exclusively in the following discussion, molecular concentration in the intercrystalline space is negligibly small in comparison with intracrystalline concentration.

A survey of the different features of molecular transportation as accessible by PFG-NMR under such conditions is provided by the propagator representation. As an example, Figure 2 shows the mean propagator of ethane in zeolite NaCaA³¹ for two different crystallite sizes at three different temperatures, determined from the measured spin echo attenuations by using the inversion of equation (6). Depending on the crystallite size, the observation time and the temperature, the observed mean propagator may be exclusively determined by intracrystalline diffusion [e.g. in Figure 2(a) at 153 K] or by migration through the bed of crystallites ['long-range' diffusion, in Figure 2(b) at 293 K]. In the intermediate range between these two limiting cases, the propagator additionally depends on the rate of molecular exchange between the intra- and intercrystalline spaces. Under appropriate conditions, PFG-NMR is therefore able to provide three different dynamic quantities: the coefficients of intracrystalline and of long-range self-diffusion, and the intracrystalline mean lifetime.

Figure 2 Propagator representation for the self-diffusion of ethane in NaCaA zeolites: (a) 40 mg g⁻¹, $R \approx 8 \mu\text{m}$; (b) 58 mg g⁻¹, $R \approx 0.4 \mu\text{m}$ ³¹

A detailed description of the procedure and examples of application may be found in the literature.^{40,49}

At sufficiently low temperatures, the thermal energy of the adsorbate molecules is not high enough to allow them to overcome the step in the potential energy from the intracrystalline to the intercrystalline space. The molecules are confined, therefore, to the interior of the individual crystallites, and the situation is comparable to that within a pore with impenetrable walls,⁵⁰ where now the pore size corresponds to the size of the crystallites. Following the scattering analogy, the PFG-NMR spin echo attenuation due to diffusion between connected pores has been used to analyze the pore distribution and connectivity.^{51,52} It is a challenge for PFG-NMR to adopt this concept to study molecular exchange between the different crystallites in the transition range between 'restricted' and long-range diffusion.

One of the most remarkable features of intracrystalline diffusion is the large variety of patterns of concentration dependence. So far, at least five different types of concentration dependence have been observed. Examples of adsorbate-adsorbent systems that follow these different patterns are presented in Figure 3.⁴⁰ It is an attractive task for molecular dynamics simulations to correlate the different patterns with possible microdynamic models.⁵³⁻⁵⁵

A large number of zeolite structure types are of noncubic symmetry, so that intracrystalline molecular migration must be described by a diffusion tensor rather than by a diffusion coefficient, i.e. a scalar quantity. As a consequence of the

Figure 3 Patterns of the concentration dependence of intracrystalline diffusivities. I, *n*-Hexane in NaX at 358 K. II, (Δ) *ortho*-, ($\square$) *meta*-, and ($\blacktriangle$) *para*-xylenes in NaX at 393 K. III, Ammonia ($\circ$) and water ($\bullet$) in NaX at 298 K. IV, Acetonitrile in NaX at 393 K. V, ($\circ$) Ethane at 173 K and (Δ) propane at 413 K in NaCaA⁴⁰

microscopic size of the crystallites, only recently have PFG-NMR measurements of diffusion anisotropy in zeolites become possible. The measurements have been carried out in two different ways: (i) by introducing the zeolite crystallites into an array of parallel capillaries with their longitudinal extension preferentially parallel to the capillary axes; and (ii) by analyzing the shape of the signal decay function.^{56,57} In both cases, the measured diffusivities (methane and ethane in zeolite ZSM-5) were found to be in satisfactory agreement with the results of molecular dynamics simulations.^{53,54}

As a noninvasive method, PFG-NMR represents an excellent tool for the in situ observation of molecular transportation under reaction conditions. As an example, Figure 4 represents the results of Fourier transform PFG-NMR measurements^{56,58} of the time dependence of the diffusivities of the reactant and the product molecules during the conversion of cyclopropane to propene on zeolite NaX.⁵⁹ In addition, Figure 4 also shows the relative amount of both species as determined by analyzing the free induction decay. Comparing the intrinsic reactivities with the rather high intracrystalline mobilities, any essential influence of molecular transport on the rates of molecular conversion in flow reactors may be excluded. Using zeolite crystallites of different size, this prediction could in fact be confirmed by direct measurement in flow reactors.⁵⁹

Since the first applications of PFG-NMR to study intracrystalline diffusion in zeolites, repeatedly dramatic differences between these data and the results of conventional sorption measurements have been stated.^{17,40} This discrepancy led to a critical reexamination of the earlier sorption data, which revealed that in many cases the effects of external heat- and mass-transfer resistances in limiting the adsorption-desorption rates were far greater than originally assumed, and the discrepancy with the NMR data could be explained on this

Figure 4 Time dependence of the relative amounts of cyclopropane and propene during the conversion of cyclopropane to propene in NaX and their self-diffusion coefficients at 473 K⁵⁹

basis. Moreover, as the PFG-NMR data are in satisfactory agreement with the results of quasielastic neutron scattering experiments⁶⁰ and with molecular dynamics simulations,^{53,54} there should be no doubt that PFG-NMR yields the correct values for the intracrystalline mobility under equilibrium conditions.

A comparison with the results of adsorption-desorption measurements is complicated by the fact that the latter experiments are carried out under nonequilibrium conditions, yielding transport- rather than self-diffusivities.⁴⁰ However, being based on the same elementary processes, i.e. the stochastic movement of the individual molecules, at least for small concentrations, agreement between the transport- and self-diffusivities should be expected. For A-type zeolites this agreement has in fact repeatedly been confirmed.^{40,61,62} Remaining differences, mainly observed for zeolites NaX and ZSM-5, are difficult to explain. Following the adsorption process of *n*-hexane in beds of zeolites NaX by space- and time-resolved PFG-NMR, the molecular mobility of the *n*-hexane molecules immediately after adsorption was found to coincide with that at equilibrium.⁶³ Therefore, as a possible explanation of this discrepancy, it must also be excluded that the diffusivities as obtained by PFG-NMR with sealed samples are only attained after some period of relaxation within the adsorbate-adsorbent system. It is one of the current tasks of zeolite research to decide whether the remaining differences are real indications of different transport properties under equilibrium and nonequilibrium conditions, or whether they are mere consequences of not yet revealed shortcomings in the experimental procedure.

Acknowledgments

The development of PFG-NMR for the study of molecular diffusion in porous media, particularly in zeolites, has profited significantly from the continuous engagement of Harry Pfeifer, one of the pioneers of NMR in Central Europe (see *Pfeifer, Harry: Leipzig, Summer 1951*). I have had the privilege of personal contact and many stimulating discussions with him over many years, and I would like to thank him for his continuous help and encouragement and for countless discussions

1 INTRODUCTION

The central idea of the pioneers of this general research was to find a molecule¹ which was nonreactive and particularly sensitive to its environment, physical interactions with other chemical species, and the nature of adsorption sites, which could be used as a probe for determining in a new way solid properties that are difficult to detect by classical physicochemical techniques. In addition, the probe needed to be detectable by NMR spectroscopy, since this technique is particularly suitable for investigating electron perturbations in rapidly moving molecules.

Xenon is this ideal probe because it is an inert gas, is monoatomic, and has a large spherical electron cloud. From the NMR point of view, the ^{129}Xe isotope has a spin of $\frac{1}{2}$, its natural abundance in xenon is 26%, and its sensitivity of detection relative to the proton is about 10^{-2} . The recent development by Pines and co-workers of xenon optical polarization techniques offers increased sensitivity by a factor of 10^3 for the detection of adsorbed xenon.^{2,3} The high polarizability of the xenon atom makes it very sensitive to its environment. Small variations in the physical interactions with the environment cause marked perturbations of the electron cloud; these are transmitted directly to the xenon nucleus and greatly affect the NMR chemical shift.

2 CHEMICAL SHIFT OF XENON ADSORBED ON A ZEOLITE

In pure xenon gas,⁴ the ^{129}Xe chemical shift can be expressed by a virial expansion of the xenon density ρ :

$$\delta(T, \rho) = \delta_0 + \delta_{1,\text{Xe}}(T) \cdot \rho_{\text{Xe}} + \delta_{2,\text{Xe}}(T) \cdot \rho_{\text{Xe}}^2 + \delta_{3,\text{Xe}}(T) \cdot \rho_{\text{Xe}}^3 + \dots \quad (1)$$

where $\delta(T, \rho)$ is the resonance shift at temperature T and density ρ . The term δ_0 is the value of the resonance shift extrapolated to an infinitely low density; $\delta_{i,\text{Xe}}(T)$ are the virial coefficients of the shift in density.

For mixtures of xenon and another gas A, Jameson et al.⁴ showed that, in the linear range,

$$\delta = \delta_0 + \delta_{1,\text{Xe}}(T) \cdot \rho_{\text{Xe}} + \delta_{1,\text{A}}(T) \cdot \rho_{\text{A}} \quad (2)$$

where ρ_{Xe} and ρ_{A} are the densities of xenon and 'solvent' molecules A, respectively; $\delta_{1,\text{Xe}}$ and $\delta_{1,\text{A}}$ characterize the Xe–Xe and Xe–A interactions, respectively.

As in the gas phase, most information has been obtained from analyzing the variation in the chemical shift with xenon concentration, generally at 26 °C. The amount of xenon adsorbed is expressed as the number of atoms N per gram of anhydrous zeolite or the number of atoms n_s per cage (zeolites Y, ZK-4, erionite, etc.).

Fraissard et al. have shown that the chemical shift of adsorbed xenon is the sum of several terms corresponding to the various perturbations that it experiences^{1,5,6}

$$\delta = \delta_{\text{ref}} + \delta_s + \delta_{\text{Xe}} + \delta_{\text{SAS}} + \delta_{\text{E}} + \delta_{\text{M}} \quad (3)$$

δ_{ref} is the reference (gaseous xenon at zero pressure). The term δ_s accounts for interactions between xenon and the surface of the zeolitic pores, assuming that the solid does not contain any electrical charge; thus it depends only on the dimensions of the cages or channels and on the ease of xenon diffusion. The term $\delta_{\text{Xe}} = \delta_{\text{Xe-Xe}} \cdot \rho_{\text{Xe}}$ accounts for Xe–Xe interactions; it increases with increasing local density of adsorbed xenon and becomes predominant at high xenon pressure. When the Xe–Xe collisions are isotropically distributed (large spherical cage) the relationship $\delta = f(N)$ is a straight line (Figure 1, curve 1). The slope, $d\delta/dn$ is proportional to the local xenon density and, therefore, inversely proportional to the 'void volume'. If the Xe–Xe collisions are anisotropically distributed (narrow channels), $d\delta/dN$ increases with N (Figure 1, curve 2).

When there are strong adsorption sites (SASs) in the void space, these interact with xenon much more than do the cage or channel walls, and each xenon atom spends a relatively long time on the SAS, particularly at low xenon concentration. The corresponding chemical shift δ_{SAS} will be greater than in the case of a noncharged structure (Figure 1, curve 3). When N increases, δ must decrease if there is fast exchange of the atoms adsorbed on the SASs with those adsorbed on other sites. When N is high enough, the effect of Xe–Xe interactions again becomes the most important factor, and the dependence of δ on N is then similar to that shown by curve 1 in Figure 1. In this case, $\delta_{N \rightarrow 0}$, (the chemical shift extrapolated to zero concentration) depends on the nature and number of these SASs. Often, these SASs are charged, and sometimes they are paramagnetic cations. The theoretical curve (3 in Figure 1), is displaced to high frequency (Figure 1, curve 4). The difference between curves 1 and 3 shows the effect (δ_{E}) of the electrical field and, if present, the effect (δ_{M}) due to the magnetic field created by these cations.¹

Figure 1 Variation in the chemical shift of xenon adsorbed on a porous solid. See text for details

3 INFLUENCE OF THE PORE STRUCTURE ON Δ_s : APPLICATION TO POROSITY

The relationship $\delta = f(N)$ is characteristic of the zeolite structure when the Si/Al ratio is very high and when there are no strong adsorption sites accessible to xenon. Figure 2 illustrates the sensitivity of this technique to the pore structure. The slopes of the curves depend on the void volume of the pores; this is logical because for a given number of xenon atoms per gram, the local density and thus the Xe–Xe interactions depend on this volume. The chemical shift δ_s at zero concentration is related to the structure; the smaller the channels or cavities, or the more restricted the diffusion, and the greater δ_s becomes.

It is assumed that at 26 °C the experimental chemical shift is the average of the shift of xenon in rapid exchange between a position A on the pore surface (denoted by δ_a) and a position in the volume V of the cavity or channel (denoted by $\langle\delta_v\rangle$):

$$\delta = \frac{N_a \delta_a + N_v \langle\delta_v\rangle}{N_a + N_v} \quad (4)$$

where N_a and N_v are the number of xenon atoms in each state. This equation is valid for any xenon concentration, and thus for $N \rightarrow 0$, $\delta \rightarrow \delta_s$.

$\langle\delta_v\rangle$ is a function of δ_a and the distance traveled by the xenon atom between two successive collisions with the pore wall. In fact, $\delta_v = \delta_a$ when the xenon leaves the surface. δ_v then decreases during the journey between two collisions, and thus the need to determine the mean value $\langle\delta_v\rangle$.

In order to obtain by ^{129}Xe NMR precise data on the void space of a zeolite of unknown structure and the dimensions

Figure 2 Chemical shift δ of adsorbed ^{129}Xe versus the number of xenon atoms per gram of solid

of structural defects, Springuel-Huet et al.⁷ have calculated the ‘mean free path’ $\bar{l}$ of xenon imposed by the structure, and determined the dependence of δ_s on $\bar{l}$, both experimentally and by calculation (sphere, infinite cylinder):

$$\delta_s = \delta_a \frac{a}{a + \bar{l}} \quad (5)$$

where a is a constant. Equation (5) can be deduced from equation (4).⁸ The large variation in δ_s with $\bar{l}$ (Figure 3) proves that ^{129}Xe NMR is very sensitive to pore dimensions.

Derouane and Nagy have been able to relate δ_a to the curvature of the adsorbing surface and, therefore, also to the pore diameter.⁵ Finally, Ripmeester et al.⁸ have continued this study by calculating the Lennard–Jones potential curves for a xenon atom and a spherical layer representing the atoms of a cage. They deduced that in small cages xenon is ‘solid like’ and in larger cages ‘gas like’, and that consequently it is difficult to imagine a single correlation between the xenon chemical shift and the dimensions of the adsorption zones.⁸

The symmetry of the adsorption site can sometimes be reflected by the form of the signal when the interactions to which the xenon atom is subjected are highly anisotropic. For example, Springuel-Huet and Fraissard have shown that the ellipsoid-shaped channels of SAPO-11 and AlPO₄-11 cause chemical shift anisotropy effects to be observed in the ^{129}Xe NMR spectra of adsorbed xenon,^{3,5} due to the similarity between the small axis of the pore section ($0.67 \times 0.39 \text{ nm}$) and the diameter of the xenon atom (0.44 nm). Similar results have been obtained by Ripmeester et al. on Xe/clathrates systems.³

Figure 3 Variation in δ_s versus the mean free path l . F, ferrierite; Z-5, ZSM-5; Z-12, ZSM-12; Z-48, ZSM-48; A-5, AIPO₄-5; A-11, AIPO₄-11; A-17, AIPO₄-17; S-34, SAPO-34; S-37, SAPO-37

When the zeolite structure includes several adsorption zones, the xenon spectrum must contain an equal number of components characteristic of these zones, provided that the diffusion of the xenon atoms is not too rapid on the NMR timescale.¹ Thus, the spectrum of sodium mordenite shows two signals at 26 °C, arising from xenon in the main channels and in the side pockets.^{1,3,5} However, because of rapid exchange of xenon between these two regions there is only one signal for H⁺-exchanged mordenite. The spectrum of ferrierite at 26 °C shows two signals characteristic of two types of channel.^{3,5} In this case it was even possible to detect the presence of a mordenite intergrowth. Two signals have also been detected for the Xe/H-Rho system, but only at a temperature as low as − 50 °C so as to avoid rapid exchange of atoms located in the octagonal prisms and the large cavities. In Cs-Rho, only the signal corresponding to the large cavities is detected, since all the prisms are occupied by Cs⁺.^{5,6}

It is clear from these examples that this ¹²⁹Xe NMR can be used to identify all the different microporous adsorption zones, namely the structure defects in zeolites,¹ heteropolyanions, solid polymers,³ clathrates,^{3,6} etc.

4 INFLUENCE OF TEMPERATURE

The study of the temperature dependence is another way of checking the size of the pores in which the xenon is adsorbed.⁹ The variation in temperature changes the relative residence times of xenon on the surface and in the free space, which in turn influence the xenon chemical shift. The variation in δ thus depends on $\langle\delta_v\rangle$. The variation is very small if $\langle\delta_v\rangle \simeq \delta_a$ (ZSM-5), and very large if $\langle\delta_v\rangle \ll \delta_a$ (Na-Y) (Figure 4).

Figure 4 Variation in δ_s versus the temperature T of the experiment

From a quantitative point of view, Chen and Fraissard⁹ have shown that

$$d \left(\ln \frac{\delta_a - \delta_s}{\delta_s - \langle\delta_v\rangle} \right) / dT = - \frac{\Delta E}{RT^2} \quad (6)$$

where ΔE is the energy difference between the xenon in the two states A and V. The fast exchange model is valid in the temperature range where the plot of $\ln [\delta_a - \delta_s / \delta_s - \langle\delta_v\rangle] = f(1/T)$ is a straight line.

5 EFFECT OF THE Si/Al RATIO OF ZEOLITES

The relationship between δ_s and the porous structure is strictly valid only for an electrically neutral surface. The chemical shift of xenon must therefore depend on the chemical composition of the zeolite, in particular on the number of charges, i.e. on the Si/Al ratio. This dependence is more pronounced when the temperature is low and the pore diameter is small (increased effect of δ_a with the contact time of xenon at the surface).

In the case of faujasite, either with Na⁺ or decationized, the $\delta = f(N)$ relationships are almost parallel straight lines at 26 °C, and $\delta_{N \rightarrow 0}$ decreases monotonically by 4 ppm when Si/Al increases from 1.28 to 54.¹ For ZSM-5 and ZSM-11 (narrow channels) the dependence of $\delta_{N \rightarrow 0}$ on the aluminum concentration is greater than for faujasite (large cavities). In addition, this variation shows a break at about [Al] = 2 Al atoms per unit cell, which demonstrates that the xenon–wall interactions change at this concentration.¹⁰ Thus aluminum is not randomly distributed in the lattice; rather, its distribution depends on the concentration. Finally, we mention the difference between the $\delta = f(N)$ relationships for ZSM-5 and ZSM-11 for [Al] ≥ 2 Al atoms per unit cell. Despite the similarity of the structures of these two zeolites, the sensitivity

of the ^{129}Xe NMR technique is sufficient to differentiate between them.

6 INFLUENCE OF CATIONS

It has been explained in Section 2 why the $\delta = f(N)$ curve goes through a minimum when there are strong adsorption sites in the zeolite. This has been shown for X and Y zeolites with divalent cations such as Mg^{2+} , Ca^{2+} , Zn^{2+} , Cd^{2+} , and Ni^{2+} ,^{1,6,11} where xenon adsorption becomes saturated within the given pressure range.

Using a fast exchange model analogous to the one proposed by Springuel-Huet et al.,⁷ but taking into account the possible presence of SASSs, Cheung et al. were able to give an analytical expression of these curves in the form:¹²

$$\delta = \frac{\alpha}{\rho} + \delta_g \cdot \rho \quad (7)$$

where ρ is the overall xenon density in the zeolite, δ_g is the $\delta_{1,\text{Xe}}$ coefficient [as in equation (1)], and α depends on the distribution of N_a and N_v [as defined in equation (4)]. The $1/\rho$ dependence results in an initial decrease in δ with increasing surface coverage, before the term linear in ρ begins to dominate. Let us consider, for example, $\text{Mg}_\lambda\text{-Y}$ and $\text{Ca}_\lambda\text{-Y}$ zeolites, dehydrated under vacuum at 500°C , where λ denotes the degree of cation exchange with Na^+ .¹ When Ca^{2+} cations are in the sodalite cage or the hexagonal prisms ($\lambda < 55\%$), δ is a linear function of the xenon concentration (as for Na-Y), regardless of the extent of dehydration of the sample. When some Ca^{2+} cations are situated within the supercages ($\lambda > 55\%$), for $\text{Ca}_\lambda\text{-Y}$ one observes values of δ (compared with Na-Y) that are greatest when λ is high, especially at low xenon concentration. According to Ito et al., the experimental value of $\delta_{N \rightarrow 0}$ for $N = 0$ is roughly proportional to the square of the electric field at the nuclei of xenon atoms adsorbed on Ca^{2+} cations.¹

According to Cheung et al., the high value of δ is not due solely to the high degree of polarization of xenon and the distortion of the xenon electron cloud by the strong electric fields created by the divalent cations. They suggest the formation of a partial bond between these two species formed by the donation of a xenon 5p electron to the empty s orbital of the divalent cation.¹² A similar model concerning electron transfer from xenon to platinum was proposed by Ito et al. to explain the large shift in δ for platinum supported on Na-Y.¹

The effect of the dehydration and rehydration of zeolites on the influence of Ca^{2+} cations can also be studied by ^{129}Xe NMR.¹ For example, the chemical shift δ and the signal width $\Delta\omega$ of xenon adsorbed on $\text{Mg}_{70}\text{-Y}$ increase with increasing dehydration of the solid. The values of δ and $\Delta\omega$ are greatest when dehydration is complete. Conversely, the spectra evolve with rehydration: for a given xenon pressure, line *a* due to xenon in the supercages containing only bare Mg^{2+} decreases in favor of line *b* corresponding to Mg^{2+} surrounded by water molecules. ^{129}Xe NMR therefore makes it possible to follow the diffusion of an adsorbate in a zeolite crystallite.

The problem is more difficult in the case of paramagnetic cations, especially when the extent of exchange is so high that the magnetic term [δ_M in equation (3)] becomes large. However, Scharf et al. have succeeded, using this technique,

in following the reduction and reoxidation of the $\text{Ni}_{7.5}\text{-Na-Y}$ zeolite desorbed under vacuum at 350°C .^{1,6} When the sample was reduced at lower temperatures (about 100°C) two types of environment for the xenon atoms were evident: one corresponding to xenon in the nickel-exchanged material, and the other corresponding to xenon in contact with Na-Y or H-Y. Reduction at higher temperatures produced a low-frequency shift of the first resonance, indicating that this environment becomes more like the environment of xenon in the Na-Y zeolite. At the highest temperature (370°C) studied, only the line corresponding to xenon in Na-Y was detected. These results prove that nickel ions are removed from the supercages upon reduction. Using this method, Scharf et al. showed that reoxidation under 80 kPa of oxygen at various temperatures does not reverse the process of reduction.

A particularly interesting case is that of faujasite-type zeolites containing Ag^+ or Cu^+ cations, the external electron structure of which is *nd*.¹¹ The ^{129}Xe NMR isotropic chemical shifts of xenon in Na-X and in the fully silver-exchanged zeolite Ag-X are shown in Figure 5. The shifts in dehydrated and oxidized Ag-X are distinctly lower than that for Na-X over the range of concentration studied. Most remarkably, the shifts decrease with concentration, down to negative values in the range -40 to -50 ppm at low xenon concentration. In contrast to these results, the samples reduced at 100°C and 300°C show high-frequency shifts with respect to Na-X. After reduction at 100°C , δ increases steadily with the number of xenon atoms per supercage (n_s) from $+100$ ppm to about $+170$ ppm for about $0.3 < n_s < 4$, whereas after reduction at 300°C the shift values are between $+140$ and $+160$ ppm for $0.1 < n_s < 1$, with a shallow minimum at about $n_s = 0.7$. In the latter case, the plot of $\delta = f(N)$ has the classical shape of zeolite-supported metals. The very unusual low-frequency shift in the case of the dehydrated and oxidized samples is due to a specific interaction of xenon with Ag^+ cations in the supercages. This shielding is due to $d_\pi\text{-}d_\pi$ back-donation from silver to xenon, involving the silver 4d and the xenon 5d orbitals.

Similar studies have confirmed that Cu^{2+} is autoreduced to Cu^+ during the dehydration of Cu-Y at 400°C , and it has been

Figure 5 ^{129}Xe NMR chemical shift versus the number of xenon atoms per supercage (n_s) for the zeolites: Na-X (400 dehydrated, ●); Ag-X (400 dehydrated, ■); Ag-X (450 oxidized, ▽); Ag-X (100 reduced ×); Ag-X (300 reduced, ▲)

shown that there are only Cu^+ ions in the supercages.¹¹ The Cu^{2+} cations are located in the sodalite cavities or the prisms.

7 CATION EXCHANGE BETWEEN DIFFERENT ZEOLITES

^{129}Xe NMR of adsorbed xenon can be used to follow the exchange of cation sites in the zones accessible to xenon in a given crystallite, and to visualize the exchange of cations between different zeolites. For example, the two peaks in Figure 6(a) at 144 and 89 ppm correspond to xenon adsorbed in dehydrated RbNa-X and Na-Y zeolites, respectively.¹³ Upon mechanical mixing at 300 K [Figure 6(b)] the intensities of the two signals decrease and a third broad signal at about 141 ppm appears. After further treatment of the mixture at 673 K and 0.01 Pa [Figure 6(c)], there is a further larger decrease in the intensities of the RbNa-X and Na-Y signals, the peak at 141 ppm disappears and two additional broad signals are seen at 128 and 109 ppm.

The two xenon resonance signals corresponding to the two pure zeolites can be restored upon cooling the sample to 200 K, which proves that the third signal in Figure 6(b) is a coalescence of two signals. The mixture obtained directly in the tube by shaking is very inhomogeneous with regards to the distribution of the crystallites of the two zeolites. There are three types of zone: pure RbNa-X, pure Na-Y, and a RbNa-X–Na-Y mixture. Because of diffusion, the three corresponding lines can be distinguished at 300 K. Consequently, the information obtained by ^{129}Xe NMR at 300 K is characteristic of macroscopic zones, i.e. zones containing several crystallites. The extent of these zones depends on the mean lifetime of the xenon atom in the crystallites compared with the NMR timescale. These zones can be reduced by lowering the temperature of the NMR experiment in order to obtain more and more localized information. The rate of exchange of xenon atoms between one crystallite and another must also depend on the crystallite size and, above all, on the barrier to diffusion to the external surface; all other things being equal, this barrier is related to the size of the windows of the cavities and channels.

Figure 6 ^{129}Xe NMR spectra of xenon adsorbed at 300 K and 80 kPa on RbNa-X and Na-Y treated at 673 K under 0.01 Pa: (a) before mixing; (b) after mixing; (c) mixture retreated at 673 K under 0.01 Pa

The low-temperature ^{129}Xe NMR spectra of xenon adsorbed on the zeolite in Figure 6(b) show that [in contrast to the case of the zeolite in Figure 6(c)], down to 200 K there are still four well-resolved peaks, two of them corresponding to the original RbNa-X and Na-Y zeolites. The other two signals located between those of RbNa-X and Na-Y should correspond to the $\text{Rb}_{58-x}\text{Na}_{24+x}\text{-X}$ and $\text{Rb}_x\text{Na}_{56-x}\text{-Y}$ zeolites, that result from ion exchange between the two original solids.

8 DISTRIBUTION OF THE ADSORBED PHASES

Gedeon et al. showed that the values of the slope $d\delta/dN$ and $\delta_{N \rightarrow 0}$ of the $\delta = f(N)$ plots for each degree of Na-Y hydration can be used to distinguish the water located in zones accessible or inaccessible to xenon, and to measure the volume of water in the pores.¹ Conversely, during adsorption the spectrum of the xenon probe is characteristic of the concentration gradient of the adsorbate in the sample tube and even that within the zeolite crystallite.

Pines and co-workers¹⁴ confirmed the interest in this technique by applying it to the study of the adsorption of various compounds (benzene, trimethylbenzene and hexane). Their results were confirmed by multiple quantum NMR spectroscopy.¹⁴

9 EFFECT OF EXTRAFRAMEWORK ALUMINUM

It is well known that extraframework aluminum Al_{NF} plays an important role in the catalytic properties of zeolites. The presence of these species is usually checked by ^{27}Al NMR spectroscopy of the dehydrated samples normally used in catalytic reactions, but the nature of these species is still unclear. Chen et al.¹⁵ have recently studied the nature of the Al_{NF} in MFI type zeolite by ^{129}Xe and ^{27}Al NMR. ^{27}Al NMR showed that the reference sample (R) did not contain any extraframework aluminum (Table 1). Conversely, the samples prepared in fluoride medium always contained some Al_{NF} . The quantity of Al_{NF} in the samples depends on the synthesis conditions.

The four samples studied by ^{129}Xe NMR (Table 1) have different xenon chemical shift δ dependences on the xenon loading N (Figure 7). For sample R, δ increases monotonically with N . For the samples synthesized in fluoride medium, δ first decreases and then increases with N . This indicates the presence of some strong adsorption sites inside the channels of the samples. These sites can only be more or less charged Al_{NF} species. Comparison of the number of Al_{NF} and the $\delta_{N \rightarrow 0}$

Table 1 Aluminum Concentration per Unit Cell

Sample	Total aluminum	Framework aluminum	Nonframework aluminum
R ^a	4.0	4.0	0
A	8.0	4.0	4.0
B	3.4	2.9	0.5
C	2.2	1.6	0.6

^aR, reference.

Figure 7 Variation in the chemical shift δ and the linewidth ΔH versus the number of xenon atoms (N) per gram of solids. Δ , A; $\bullet$, B; $\square$, C; * R. See Table 1

value shows that the charge on Al_{NF} increases in the order $\text{A} < \text{B} < \text{C}$. The average charge on each Al_{NF} atom depends on the amount of Al_{NF} and on the $\text{Al}_{\text{NF}}/\text{Al}_{\text{F}}$ ratio inside the zeolite.

10 CONCLUSIONS

Using ^{129}Xe NMR spectroscopy with adsorbed xenon as a probe, it is possible:

1. To determine the dimensions and the forms of the internal free volumes of zeolites without knowing their structures:¹⁶ (a) to reveal structure defects produced by, for example, dealumination, and to determine their characteristics; and (b) to calculate the short-range crystallinity, as opposed to that determined by X-ray crystallography.
2. To follow the mechanism of the synthesis and crystallization of zeolites during their preparation.¹⁷
3. To locate cations in the zeolite structure and to follow their migration or a change in their environment, depending on various factors.
4. To locate any 'encumbering' species, e.g. adsorbed molecules, extraframework species, coke formed during catalytic cracking reactions.¹⁸
5. To determine the dispersion of metals (particularly when the particles are too small to be detected by electron microscopy),¹⁹ and the distribution of the molecules adsorbed on the particles (as opposed to the mean coverage).

6. To compare the diffusion of species as a function of the size of the zeolite 'windows'.²⁰

The above list of applications is not exhaustive. Indeed this technique can also be applied to any microporous system (amorphous solid, polymer, clay, etc.), provided that one works at low temperature.

1 ZEOLITES: STRUCTURE AND PROPERTIES

Molecular sieves are a class of porous open-framework solids which includes aluminosilicates (zeolites), aluminophosphates, and related materials. Zeolites^{1–3} are built from corner-sharing SiO_4 and AlO_4 tetrahedra linked by the apical oxygen atoms to form frameworks of high internal surface area with regular channels and cavities of molecular dimensions. The zeolitic channel systems, which may be one-, two- or three-dimensional, may occupy more than 50% of crystal volume. Their microporous structure enables zeolites to be used as molecular sieves, as they can only adsorb molecules of certain size. The net negative charge of the framework, equal to the number of the constituent aluminum atoms, is balanced by exchangeable cations M^{n+} located in the channels which normally also contain water. The name ‘zeolite’ (from the Greek $\zeta\epsilon\omega$ = to boil and $\lambda\iota\theta\sigma$ = stone) was coined by Cronstedt⁴ to describe the behavior of the mineral stilbite which rapidly loses water on heating and thus seems to boil.

The general oxide formula of a zeolite is $\text{M}_{x/n}\text{-(AlO}_2)_x(\text{SiO}_2)_y \cdot m\text{H}_2\text{O}$, with $y \geq x$. According to the Loewenstein rule,⁵ which applies to all hydrothermally synthesized zeolites, aluminate tetrahedra cannot be neighbors in the framework, and so Al–O–Al linkages are forbidden. There are about 40 identified zeolite minerals (with $1 \leq y/x \leq 5$) and at least 140 synthetic species with a wide range of compositions. Figure 1 shows the secondary building units and some of the cages

Figure 1 (a) Secondary building units in zeolite structures. (o) Positions of tetrahedral silicon and aluminum atoms; oxygen atoms (not shown) lie approximately halfway between them. (b) Some polyhedra found in zeolite frameworks: the ‘ α -cage’ (26-hedron of type I); the sodalite cage; double eight-membered ring; double six-membered ring (hexagonal prism); the 18-hedron (‘ γ -cage’); the 11-hedron (‘ ϵ -cage’ or ‘cancrinite cage’)

found in molecular sieves, and Figure 2 illustrates framework structures based on the sodalite cage.

Zeolites are prepared under mild (60–400 °C) hydrothermal conditions in strongly basic media. The type and concentration of the base are important structure-directing factors, and a variety of organic bases (usually secondary or tertiary amines or quaternary ammonium compounds) have been used. A preparative method utilizing low pH which relies on F^- anions to solubilize the reactants as complex fluorides has recently been developed. Other elements, such as Ga, Ge, B, Fe, and P can substitute for Si and Al in the framework.

The physical and chemical behavior of zeolites is the subject of various monographs.^{6–10} The most important properties are the ability to adsorb organic and inorganic substances and to act as cation exchangers and catalysts. Depending on the pore diameter and the molecular dimensions, species such as gaseous elements, ammonia, alkali metal vapors, hydrocarbons, and many other organic and inorganic species may be accommodated in the intracrystalline space of dehydrated zeolites. This process, known as ‘molecular sieving’, is a powerful method for the resolution of mixtures. Commercial applications include the drying of organics, separation of hydrocarbons and of N_2 and O_2 in air, and the removal of NH_3 and CS_2 from industrial gases.

Cations neutralizing the electrical charge of the aluminosilicate framework can be exchanged for other cations from solution. Zeolites often possess selectivities for certain cations, and

Figure 2 (a) The truncated octahedron, more correctly a tetrakaidodecahedron (also known as 'sodalite cage' or 'β-cage'). (b) The structure of zeolite A is formed by linking the sodalite cages through double four-membered rings. (c) The structure of sodalite is formed by direct face-sharing of four-membered rings in the neighboring sodalite cages. (d) The faujasite structure is formed by linking the sodalite cages through double six-membered rings. For clarity, exchangeable non-framework cations are not shown

this is used for their isolation and concentration. Applications include the removal of ammonia from sewage and agricultural effluents, collection of harmful products of nuclear fission (such as $^{137}\text{Cs}^+$ and $^{90}\text{Sr}^{2+}$), water softening, and the recovery of precious elements. Molecular sieving properties of zeolites are further modified by ion exchange. Thus zeolite Na-A sorbs both N_2 and O_2 , while Ca-A sorbs nitrogen preferentially to oxygen.

However, the ability to catalyze a wide range of reactions, such as cracking, hydrocracking, oxidation, and isomerization of hydrocarbons, overshadows all other applications of zeolites. Rare-earth exchanged and hydrogen forms of some zeolites (such as zeolite Y) have a cracking activity which is orders of magnitude greater than that of conventional silica/aluminas.¹¹ The synthetic zeolite ZSM-5,¹² is a particularly powerful catalyst (Figure 3). Its high silica content (the Si/Al ratio is typically 30) gives it high thermal stability,

Figure 3 The structure of ZSM-5/silicalite

while the channel diameter is convenient for many applications. Catalytic properties of ZSM-5 include the ability to synthesize gasoline from methanol in a single step. Silicalite, a material which is isostructural with ZSM-5, but contains only small amounts of aluminum, is, by contrast to other zeolites, hydrophobic and organophilic, and is used in the removal of dissolved organics from water. The annual industrial consumption of zeolites is about 550 000 ton, of which 135 000 ton are used in catalysis, 375 000 ton as ion exchangers in detergent powders, and 40 000 ton as sorbents.

Synthetic zeolites are usually microcrystalline and, furthermore, typically contain four 10-electron atomic species (Si^{4+} , Al^{3+} , O^{2-} and Na^+), which makes their structure difficult to study by conventional methods. High-resolution solid state NMR techniques, such as magic angle spinning (MAS), gave zeolite chemistry a powerful structural tool for monitoring all elemental components of such frameworks.

2 COMPOSITION OF ZEOLITIC FRAMEWORKS AND THE NATURE OF EXTRAFRAMEWORK ALUMINUM

Framework silicon in zeolites is 4-coordinate, and thus there are five different possible environments of a silicon atom: $\text{Si}(\text{OAl})_4$, $\text{Si}(\text{OAl})_3(\text{OSi})$, $\text{Si}(\text{OAl})_2(\text{OSi})_2$, $\text{Si}(\text{OAl})(\text{OSi})_3$, and $\text{Si}(\text{OSi})_4$. For simplicity, we denote these by $\text{Si}(n\text{Al})$ where n (≤ 4) is the number of aluminum atoms connected, via oxygen atoms, to a silicon. Each type of $\text{Si}(n\text{Al})$ building block corresponds to a definite range of ^{29}Si chemical shift (Figure 4).¹³ When a ^{29}Si MAS NMR spectrum of a zeolite contains more than one peak and is correctly assigned in terms of $\text{Si}(n\text{Al})$ units, the Si/Al ratio in the zeolitic framework may be calculated from the spectrum alone. Because of the absence of Al–O–Al linkages, the environment of every aluminum atom is $\text{Al}(4\text{Si})$. Each Si–O–Al linkage in an $\text{Si}(n\text{Al})$ unit incorporates 0.25 aluminum atoms, and the whole unit contains $0.25n$ aluminum atoms. The Si/Al ratio may therefore be

Figure 4 Ranges of ^{29}Si chemical shift for $\text{Si}(n\text{Al})$ building blocks in zeolites. The $\text{Si}(4\text{Al})$ range in some synthetic sodalites containing various enclathrated salts is exceptionally wide, from -76.5 to -97 ppm

calculated directly from the ^{29}Si MAS NMR spectrum using the formula¹⁴

$$(\text{Si}/\text{Al})_{\text{NMR}} = \frac{I_4 + I_3 + I_2 + I_1 + I_0}{I_4 + 0.75I_3 + 0.5I_2 + 0.25I_1} \quad (1)$$

where I_n is the intensity (peak area) of the NMR peak corresponding to the $\text{Si}(n\text{Al})$ building unit. By comparing values of $(\text{Si}/\text{Al})_{\text{NMR}}$ with the results of chemical analysis, which gives bulk composition, the amount of extraframework aluminum in chemically modified zeolites can be calculated.

Equation (1) applies to all zeolites with framework Si/Al ratios less than about 10.^{14–16} It can also serve as a test for the correctness of spectral assignment. Its validity has been confirmed in the case of zeolites X and Y, which can be synthesized in a range of compositions. The spectra can be deconvoluted using Gaussian peak shapes, and the areas of the individual deconvoluted peaks used in equation (1). However, equation (1) cannot be applied directly to spectra containing overlapping peaks from $\text{Si}(n\text{Al})$ units of crystallographically inequivalent silicon atoms, to zeolites containing framework defects (nests of hydroxyl groups), or to dealuminated zeolites in which vacancies created by the expulsion of framework aluminum have not subsequently been resubstituted by silicon. As aluminum is removed, the number of $\text{Si}(0\text{Al})$ (i.e. $\text{Si}(4\text{Si})$) units is unchanged, while $\text{Si}(3\text{Al},1\text{Si})$ units, for example, give rise not to $\text{Si}(2\text{Al},2\text{Si})$ and $\text{Si}(1\text{Al},3\text{Si})$ units, but to $\text{Si}(2\text{Al},1\text{OH})$ and $\text{Si}(1\text{Al},2\text{OH})$ groupings, the ^{29}Si NMR peaks from which overlap with those from $\text{Si}(n\text{Al})$ groupings. Although the intensities of ^{29}Si peaks corresponding to silicon atoms linked to one or more hydroxyl groups are enhanced by

Figure 5 High-resolution ^{29}Si MAS NMR spectra of synthetic zeolites Na-X and Na-Y.¹⁵ $\text{Si}(n\text{Al})$ peaks are identified by the n above the peaks

^1H – ^{29}Si cross polarization, their individual intensities cannot be determined easily because the efficiency of the technique depends on the distance between the silicon and the hydrogen atoms.

^{29}Si MAS NMR can also be used to determine the ordering of silicon and aluminum in the framework. The areas under the peaks in the deconvoluted spectrum are proportional to the populations of the corresponding structural units in the sample. It is therefore possible to compare the experimental data (Figure 5) with the relative numbers of such units in models involving different silicon/aluminum ordering schemes. For most Si/Al ratios more than one ordering scheme is compatible with the $\text{Si}(n\text{Al})$ intensities determined by ^{29}Si MAS NMR. The choice between the various schemes is made on the basis of: (a) the degree of agreement between the spectral intensities and those required by the given model; (b) compliance with crystal symmetry requirements; and (c) minimum electrostatic

Figure 6 Two of the possible silicon/aluminum ordering schemes for zeolite Y with Si/Al = 1.67.¹⁵ (○) Silicon atoms; (●) aluminum atoms. The ratio of intensities Si(4Al):Si(3Al):Si(2Al):Si(1Al):Si(0Al) corresponding to each scheme is given in the upper right-hand corner. E is the calculated electrostatic energy for the double cage in units of $(qe)^2/a$, where a is the T–O–T distance. The asterisk denotes the preferred scheme

repulsion within the framework. Figure 6 shows the preferred ordering schemes for Si/Al = 1.67.

Many ^{29}Si spectra of natural and synthetic zeolites have been measured by various workers since the pioneering papers by Lippmaa et al.¹³ and Engelhardt et al.¹⁴ appeared. The

results for zeolites, the spectra of which can be directly assigned to Si(n Al) units, are listed in Table 1.

3 RESOLVING CRYSTALLOGRAPHICALLY NONEQUIVALENT TETRAHEDRAL SITES IN ZEOLITES

In naturally occurring zeolites, the Si/Al ratio is less than about 5, but materials with lower aluminum contents can be prepared synthetically. One might expect an uncomplicated spectrum for such materials, containing the Si(0Al) peak, sometimes with a smaller Si(1Al) resonance, depending on the Si/Al ratio. The discovery¹⁷ that the spectrum of ZSM-5/silicalite, which has a very low aluminum content and the structure shown in Figure 3, has considerable fine structure was therefore a surprise. The fine spectral detail arises from crystallographically inequivalent tetrahedral environments of the Si(4Si) sites. Figure 7(a) shows a spectrum in which as many as 19 individual lines can be separately resolved, the linewidth of the narrowest line being only about 5 Hz.¹⁸ The room temperature spectrum may be simulated by 24 Gaussian peaks, and the unit cell of ZSM-5/silicalite contains 24 inequivalent silicon sites.

X-ray diffraction (XRD) shows that silicalite can exist in the monoclinic and the orthorhombic forms. ^{29}Si MAS NMR detects minute temperature-induced variations in atomic positions^{18–21} which do not necessarily involve symmetry changes detectable by XRD. The spectra are sensitive even to small temperature changes and reveal the corresponding

structural transformations. Above 363 K silicalite contains only 12 inequivalent silicon sites, and the spectrum shown in Figure 7(c) can be simulated using Gaussian peaks of total intensity 12. Figure 7 also shows that the addition of small amounts of adsorbed organics to dehydrated silicalite induces similar changes in the spectra.

^{29}Si spectral peaks from most synthetic zeolites cannot easily be linked to specific silicon sites because the $\text{Si}(n\text{Al})$ manifolds from inequivalent sites overlap. However, when the ammonium form of a highly siliceous zeolite is heat treated in the presence of water vapor so that most framework aluminum is removed, the resolution of the ^{29}Si spectrum improves considerably.^{22,23} Figure 8 shows the spectra of several zeolites before and after hydrothermal treatment. The intensities of the two peaks in the spectra of the siliceous zeolites omega and offretite are in a 2:1 ratio corresponding to the two inequivalent tetrahedral sites in the same population ratio. Mordenite, on the other hand, has four inequivalent sites in a 2:1:1:2 population ratio, so that the peak at -115 ppm in Figure 8 is a composite.

The fact that the ^{29}Si chemical shift is related to the T–O–T angles in zeolitic frameworks is useful for structural

Figure 8 ^{29}Si MAS NMR spectra of (above) zeolites Y, omega, offretite and mordenite; and (below) their dealuminated forms²²

determination.^{22,24} Chemical shifts in framework silicates have been correlated with the mean Si–O bond distances, and relationships have been developed which are in good agreement with the results of semiempirical calculations of chemical shift. A quantum mechanical rationalization of the correlation between the ^{29}Si chemical shift in framework silicates and the change in the s character of the oxygen orbitals in the Si–O–Si bond has also been proposed (see Figure 9). The observed correlation between chemical shifts of $\text{Si}(4\text{Si})$ units and mean bond angles has been explained²⁵ in terms of a quantum mechanical model and confirmed by an extended set of experimental data consistent with relationships involving θ , $\cos \theta/(\cos \theta - 1)$, $\sin(\theta/2)$ and $\sec \theta$. These arguments have been extended to all five $\text{Si}(n\text{Al})$ units,²⁶ giving an approximately linear semiempirical relationship between the chemical shift of $\text{Si}(n\text{Al})$ peaks and the nonbonded $\text{Si}\cdots\text{T}$ distance (T = Si or Al) calculated from the T–O–T angle.

^{29}Si MAS NMR peaks in the spectra of certain zeolites lead to incorrect values of $(\text{Si}/\text{Al})_{\text{NMR}}$ when assigned to individual $\text{Si}(n\text{Al})$ units, as described above. When the difference in chemical shifts between peaks from inequivalent $\text{Si}(n\text{Al})$ units with the same value of n [8.4 ppm in the case of $\text{Si}_A(0\text{Al})$ and $\text{Si}_B(0\text{Al})$ in zeolite omega] is similar to the shift difference between $\text{Si}(n\text{Al})$ and $\text{Si}[(n \pm 1)\text{Al}]$ units, the effects

Figure 9 The mean T-O-T angle versus the isotropic ^{29}Si chemical shift for amorphous silica and several purely siliceous equivalents of zeolites

of aluminum substitution and crystallographic inequivalence overlap. The peaks are composites, and their intensities $I_{\text{Si}(n\text{Al})}$ cannot be read off the spectrum directly. In the case of 'as-prepared' zeolite omega, the spectrum (Figure 8) is the sum of two overlapping families of peaks. When this is taken into account, the entire spectrum can be correctly assigned and interpreted.

The chemical shift of ^{129}Xe NMR is very sensitive to the environment. When xenon is adsorbed inside a molecular sieve, its chemical shift is affected by the size and shape of the pores, by xenon-xenon collisions, by the presence of strong adsorption sites, paramagnetic species, adsorbed molecules, and phase transitions.²⁷ Most of the work in this area was done by Fraissard in Paris. While the initial hopes of predicting pore dimensions of unknown structures from ^{129}Xe NMR are still unfulfilled, the technique does provide valuable information, particularly where structural information is absent.

4 TWO-DIMENSIONAL NMR SPECTRA OF ZEOLITIC FRAMEWORKS

Two-dimensional solid state NMR techniques have been used to assign the individual NMR peaks to specific crystallographic sites. Figure 10 shows a ^{29}Si COSY-45 spectrum of the

Figure 10 Two-dimensional ^{29}Si COSY-45 spectrum of the orthorhombic form of zeolite ZSM-5/silicalite with adsorbed *p*-xylene¹⁸

orthorhombic form of zeolite ZSM-5/silicalite with adsorbed *p*-xylene.¹⁸ Of the expected 22 ^{29}Si -O- ^{29}Si connectivities, 12 are present in the spectrum. The corresponding ^{29}Si 2D INADEQUATE spectrum (Figure 11) is superior, with as many as 21 connectivities being observed.¹⁸ Excitation of a double quantum coherence has been used in double quantum filtered COSY, as in the experiment using a ^{29}Si -enriched sample of the highly siliceous zeolite ZSM-39²⁸ which contains three kinds of silicon site in a 1:4:12 population ratio. The most intense spectral peak is split into three components of equal intensity, which indicates loss of face centering of the $Fd3m$ unit cell, resulting in the disappearance of the three-fold symmetry axis.

J-scaled COSY scales up the scalar splittings between the cross-peak components, thereby enhancing cross-peak intensities and consequently improving spectral resolution between adjacent diagonal and cross peaks. The ^{29}Si *J*-scaled COSY spectrum²⁹ measured with a scaling factor of 5 at natural isotopic abundance allows the resonances from highly siliceous mordenite to be assigned unambiguously, something which cannot be done by means of one-dimensional spectra or by conventional COSY.

Figure 11 ^{29}Si two-dimensional INADEQUATE spectrum of the orthorhombic form of zeolite ZSM-5/silicalite with adsorbed *p*-xylene¹⁸

5 DEALUMINATION AND REALUMINATION OF ZEOLITES

Solid state ^{27}Al MAS NMR spectra of 'as-prepared' zeolites normally contain a single peak corresponding to four-coordinate aluminum. Its position as measured in a 9.4 T magnetic field ranges, for different materials, from about 51 to about 65 ppm from $\text{Al}(\text{H}_2\text{O})_6^{3+}$. When the correction is made for the second-order quadrupole interaction, the chemical shift is found to be related to structural parameters in a similar manner to ^{29}Si chemical shifts. ^{27}Al MAS NMR spectra of 'as-prepared' zeolites are thus much simpler than their ^{29}Si counterparts. This is a direct consequence of the fact that while five types of $\text{Si}(n\text{Al})$ environments are possible for the silicon atom, only one possibility, $\text{Al}(4\text{Si})$, exists for the aluminum. However, while the coordination of silicon in zeolites is always four-fold, aluminum can be four-, five- or six-coordinate. The latter resonates at about 0 ppm from $\text{Al}(\text{H}_2\text{O})_6^{3+}$ and is often subject to large quadrupole interactions. Quantitatively reliable ^{27}Al spectra are obtained with fast MAS at very high magnetic fields and using strong rf pulses with small flip angles.

Since Brønsted acid groups in zeolites are associated with framework aluminum, their catalytic activity depends on the

Figure 12 ^{27}Al (MAS at 12–13 kHz) and ^1H - ^{27}Al CP MAS (MAS at 8–10 kHz) NMR spectra of increasingly dealuminated (from bottom to top) zeolite HY.⁸⁰ The Si/Al ratios calculated from ^{29}Si MAS NMR spectra and the cubic unit cell parameters a_0 are indicated. Asterisks denote spinning sidebands

concentration and location of aluminum in the structure. It is often desirable to reduce the aluminum content of the zeolitic framework. Upon hydrothermal treatment of zeolite $\text{NH}_4\text{-Y}$, the process known as 'ultrastabilization', part of the aluminum is ejected from the framework into the intracrystalline space, and the vacancies are reoccupied by silicon from other parts of the crystal. As a result, thermal stability of the zeolite is greatly increased. Ultrastable zeolite Y has been examined by ^{29}Si and ^{27}Al MAS NMR.^{30–32} ^{29}Si spectra of ultrastable zeolite Y clearly show that aluminum is removed from the framework, and that the resulting vacancies are subsequently reoccupied by silicon. ^{27}Al MAS NMR shows how six-coordinate nonframework aluminum species (Al^{NF}) build up at the expense of the four-coordinate framework aluminum (Al^{F}) as the calcination temperature is increased, and ^1H - ^{27}Al CP MAS NMR spectra of dealuminated samples help to elucidate the nature of Al^{NF} .³³ Figure 12 shows that the intensity of the peaks at 0 and 30 ppm increases relative to the peak at 60 ppm. This indicates that the 30 ppm peak is a separate ^{27}Al resonance from five-coordinate aluminum.

The process of ultrastabilization of zeolite Y can be reversed by a hydrothermal treatment with aqueous solutions of strong bases.³⁴ NMR indicates that aluminum atoms originally eliminated from the framework can be subsequently reinserted into the framework. ^{29}Si MAS spectra of dealuminated samples reflect the removal of framework aluminum from the parent sample. In the spectra of samples treated with KOH the intensities of the $\text{Si}(0\text{Al})$ peaks are greatly reduced, and the intensities of the $\text{Si}(1\text{Al})$, $\text{Si}(2\text{Al})$, $\text{Si}(3\text{Al})$, and $\text{Si}(4\text{Al})$ peaks are correspondingly increased, signifying that an aluminum has reentered the framework. The spectra of realuminated samples are very different from that of the parent material, despite the fact that their overall composition is similar. This demonstrates that the silicon/aluminum distribution among the tetrahedral sites is different. ^{27}Al quadrupole nutation NMR offers further insights into the dealumination–realumination process.^{35,36}

6 NMR STUDIES OF THE STRUCTURE OF BRØNSTED ACID SITES IN ZEOLITES

The study of acidic surface sites capable of donating protons to adsorbed molecules is crucial to heterogeneous catalysis. It is vital to know the concentration, strength, and accessibility of the Brønsted and Lewis acid sites and the details of their interaction with the adsorbed organics. The Brønsted acidity of zeolites arises from the presence of accessible hydroxyl groups associated with framework aluminum ('structural hydroxyl groups'). Extensive ^1H MAS NMR measurements of zeolites have led to the assignment of the various proton resonances. ^1H NMR of static samples can probe the geometry of the Brønsted acid site and determine the Al–H distance, because the second moment of the broadline proton spectra, which is inversely proportional to the sixth power of the distance between the dipole-coupled nuclei, is dominated by the ^1H – ^{27}Al interaction.

^{15}N NMR of molecules sorbed on zeolites is also useful for the study of zeolitic acidity, as the nitrogen atom in molecules such as ammonia and pyridine binds directly to the acid site. The ^{15}N chemical shift of ammonia adsorbed in ultrastable zeolite Y does not depend on the amount absorbed and is similar to that in liquid ammonia. Consideration of the equilibrium between the surface sites and the sorbate allows the resonance shifts for the surface complexes to be obtained. The formation of pyridinium ions in ultrastable zeolites has led to direct determination of the number of interacting hydroxyl groups. Acetonitrile has also been used to characterize the interactions with the acid sites.

When trimethylphosphine is used as a probe molecule in zeolite H-Y,³⁷ the ^{31}P MAS NMR spectrum contains resonances from at least two types of $(\text{CH}_3)_3\text{PH}^+$ complex: an immobilized complex coordinated to hydroxyl protons, and a highly mobile one which desorbs at 300 °C.

7 GALLOSILICATE AND BOROSILICATE ZEOLITES

Tetrahedral aluminum and silicon in the zeolitic framework can be substituted by several other elements. (Si,Ga)-, (Ge,Al)- and (Ge,Ga)-zeolites are structurally similar to their silicon/aluminum counterparts. ^{29}Si MAS NMR spectra of (Si,Ga)-sodalites and (Si,Ga)-faujasites^{38,39} allow (Si/Ga)_{NMR} ratios to be calculated from a formula similar to equation (1), which shows that no Ga–O–Ga linkages are present. The distribution of Si(*n*Ga) peak intensities in gallosodalite is different from the Si(*n*Al) in aluminosilicate zeolites of similar Si/T ratio (T = Al or Ga), indicating that the distribution of silicon and gallium is different from the distribution of silicon and aluminum. The ^{29}Si chemical shifts in silicon/gallium zeolites span 25.1 ppm, a wider range than in the corresponding aluminosilicates (18.5 ppm).

Borosilicate ZSM-5 ('boralite') containing up to five boron atoms per unit cell has been prepared. ^{11}B spectra show that four-coordinate boron resonates at about –3.5 ppm from $\text{BF}_3\cdot\text{OEt}_2$.⁴⁰ On dehydrating boralite, the intensity of the line decreases reversibly and a second broad line appears. The width of that line, assigned to trigonal boron, is dependent on the magnetic field intensity, which indicates that the effect is quadrupolar in nature.⁴¹

8 CHEMICAL STATUS OF GUEST ORGANICS IN ZEOLITES

The declining oil reserves have stimulated efforts aimed at converting methanol (MeOH) into higher molecular weight organics over shape-selective catalysts, particularly zeolite H-ZSM-5 which is capable of converting MeOH to hydrocarbons up to C_{10} . The mechanism of the reaction is a subject of some controversy. ^1H NMR has been used⁴² to monitor the chemistry of MeOH adsorbed on ZSM-5 inside sealed capsules which can be spun in the MAS probehead.

The ^1H MAS NMR spectrum of MeOH adsorbed on zeolite H-ZSM-5 contains peaks at 4.1 and 9.1 ppm, from methyl and hydroxyl protons, respectively. The large high-frequency (downfield) shift of the latter resonance is caused by very strong hydrogen bonding and/or direct protonation of the alcohol, and serves as a measure of the proton donating ability of the solid acid catalyst: in zeolites H-Y and H-L the shifts are considerably smaller than in ZSM-5.

9 IN SITU STUDIES OF CATALYTIC REACTIONS ON ZEOLITES

^{13}C MAS NMR can probe the kind and quantity of chemical species present inside the particle in the course of the conversion of MeOH to gasoline on zeolite ZSM-5. This information is usefully compared with the composition of the gaseous products.⁴³ These experiments have: (i) identified 29 different organic species in the adsorbed phase and monitored their fate during the course of the reaction; (ii) observed directly different kinds of shape selectivity in a zeolite; and (iii) unequivocally distinguished between mobile and attached species.

The spectrum of a sample with adsorbed MeOH and maintained at 20 °C, contains a single resonance at 50.8 ppm due to MeOH (Figure 13). After heating the sample to 150 °C the spectrum is composed of two peaks, at 50.5 and 60.5 ppm, corresponding to MeOH and dimethyl ether (DME), respectively. In a sample treated at 300 °C for 35 min, MeOH and DME have been completely converted to a mixture of aliphatics and aromatics.

Two-dimensional ^{13}C spectra can determine the connectivity of carbon atoms and the number of protons attached to each carbon atom in the various products, enabling firm assignments for many resonances to be made.⁴⁴ For example, the line at –10.7 ppm in Figure 14 is split into five components with a requisite intensity ratio, which confirms that it must be due to adsorbed methane. Spin diffusion ^{13}C NMR spectra further confirm the spectral assignments and provide new details on distribution of hydrocarbons in the intracrystalline space.

10 DIRECT OBSERVATION OF SHAPE SELECTIVITY

The distribution of adsorbed species in the sample of ZSM-5 with adsorbed methanol treated at 300 °C is different from the thermodynamic equilibrium distribution and from the distribution of the reaction products.⁴³ The main species found in the adsorbed phase are *o*- and *p*-xylene, 1,2,4,5-tetramethylbenzene, 1,2,4-trimethylbenzene,

Figure 13 Solid state ^{13}C NMR spectra reveal the successive steps in the conversion of methanol to gasoline over zeolite ZSM-5. The methanol, resonating at 50 ppm, is first dehydrated to DME (60 ppm). Subsequent carbon-carbon bond formation leads to a host of aliphatic (–10 to 35 ppm) and aromatic (not shown) compounds⁴³

and 1,2,3,5-tetramethylbenzene. The fact that 1,2,3- and 1,3,5-trimethylbenzenes are not found among the products, but are present in the adsorbed phase, while the smaller 1,2,4-trimethylbenzene is found in both, demonstrates the reality of the concept of product selectivity. The two larger isomers are unable to diffuse out of the crystal. The distribution of the tetramethylbenzenes in the intracrystalline space (none of which are found in the products of the reaction at 300 °C) is equally unexpected.

11 STRUCTURE OF ALUMINOPHOSPHATE MOLECULAR SIEVES

The AlPO_4 molecular sieves, the porous crystalline equivalents of aluminum phosphate, are built from alternating AlO_4 and PO_4 tetrahedra.^{45,46} Some of them have the framework topologies of known zeolites, but many are novel structures. The various AlPO_4 structure types are listed in Table 2, and the structures of AlPO_4 -5 and AlPO_4 -11 are shown in Figure 15. Synthesized from gels containing sources of aluminum, phosphorus, and at least one organic structure-directing template, AlPO_4 materials have electrically neutral frameworks and thus no exchangeable cations. Incorporation

^aAlso known as AlPO_4 -54.

^bAn all-silica analog of AlPO_4 -5 (known as SSZ-24) has recently been synthesized.

of a silicon source into the synthesis gel results in the formation of silicoaluminophosphates (SAPOs)⁴⁷ and the incorporation of a metal Me (such as Mg, Mn, Fe, Co or Zn), into AlPO_4 and SAPO gives the MeAPO and MeAPSO sieves, respectively.⁴⁸ SAPO and MeAPO have negatively charged frameworks, and thus potential uses as ion exchangers and catalysts. In SAPO the predominant substitution mechanism is of silicon onto phosphorus sites, though pairwise substitution of silicon onto both aluminum and phosphorus sites is also possible. In MeAPO the metal substitutes onto the aluminum sites of the equivalent AlPO_4 structure. Other elements (Li, Be, B, Ti, Ga, Ge and As) have been claimed to substitute into the aluminophosphate framework to give EIAPO materials.⁴⁹ By

Figure 14 Heteronuclear two-dimensional J -resolved ^{13}C MAS NMR spectrum of zeolite H-ZSM-5 with adsorbed methanol treated at 300°C for 30 min⁴⁴

introducing more than one kind of heteroatom into the framework, or a metal and silicon simultaneously, MeAPSO and ElAPSO sieves were prepared.^{50,51}

Remarkable AlPO_4 and related materials include VPI-5, the topology of which had been predicted in advance of its being synthesized, and cloverite, a gallophosphate molecular sieve with 20-membered rings, the most porous molecular sieve prepared so far.

12 NMR STUDIES OF AlPO_4 -5, AlPO_4 -11, AND AlPO_4 -21

The AlPO_4 materials are a challenge to multinuclear solid state MR, given the wide variety of new crystal structures and the fact that they contain two different kinds of 100% abundant nuclei (^{31}P and ^{27}Al) in close proximity. Furthermore, framework aluminum in AlPO_4 can be linked to one or two oxygen species such as $-\text{OH}$ or $-\text{OH}_2$, so that some of the aluminum atoms may be five- or six-coordinate with respect to oxygen. Another challenge are the strong quadrupolar effects involving ^{27}Al as a result of which the quadrupole correction to chemical shifts is much larger than in zeolites. The aluminum and phosphorus atoms alternate in the frameworks of all AlPO_4 , so that only even-numbered

rings may be formed. However, the three allowed coordination numbers of aluminum make possible a wide range of new structures.

Table 3 summarizes the ^{31}P chemical shifts in AlPO_4 materials. Note that the precise value of the chemical shift often depends on the kind of organic template and on the water content of calcined samples. A similar table for ^{27}Al chemical shifts cannot be readily provided as the quadrupole coupling parameters, necessary if the quadrupole correction is to be made, are rarely known. Corrected ^{27}Al chemical shifts are between 37 and 48 ppm for $\text{Al}(\text{OP})_4$ sites, about 15 ppm for $\text{Al}(\text{OP})_4(\text{OH})$, and between -9.5 and -12 ppm for $\text{Al}(\text{OP})_4(\text{OH}_2)_2$ sites.⁵² There is a recent review of AlPO_4 -based molecular sieves.⁵³ A correlation between chemical shift and bond angle for AlPO_4 materials⁶⁵ relies on the comparison of mean $\text{Al}-\text{O}-\text{P}$ bond angles with ^{27}Al chemical shifts corrected for the second-order quadrupole interaction. The imperfection of the correlation⁶⁶ is probably caused by the presence of five- and six-coordinate aluminum.

The spectra of AlPO_4 -5, AlPO_4 -11, AlPO_4 -17, and AlPO_4 -31 are consistent with known framework structures. ^{31}P and ^{27}Al MAS spectra of AlPO_4 -5 each consist of a single peak.^{54,55} The ^{31}P chemical shift (about -30 ppm) is characteristic of the $\text{P}(\text{OAl})_4$ environment. The corrected chemical shift of the broad ^{27}Al peak is about 44 ppm, which is characteristic of four-coordinate $\text{Al}(\text{OP})_4$ sites. This

^aMeasured in an equivalent SAPO structure.

means that aluminum and phosphorus strictly alternate in the framework. The ^{31}P peak from the calcined and partially hydrated form is split as a result of the interaction between the framework and the intracrystalline water, presumably giving rise to $\text{Al}(\text{OP})_4(\text{OH}_2)_2$ environments. Hydration produces significant amounts of six-coordinate framework aluminum which returns to four-coordination upon rehydration. Four- and six-coordinate aluminum resonate at 23–31 ppm and about −17 ppm, respectively.

AlPO_4 -11 has an orthorhombic unit cell, but the symmetry of the hydrated calcined material is lower. Adsorbates such as cyclohexane stabilize the higher symmetry form which has three distinct crystallographic sites for both aluminum

and phosphorus in the population ratio of 2:2:1. The lower symmetry form requires five sites in the population ratio of 1:1:1:1:1. Figure 16 shows that the ^{27}Al and ^{31}P NMR spectra of ‘as-synthesized’ AlPO_4 -11 show single asymmetric peaks (suggesting that more than one environment is present). The relatively low intensity resonance at −5.5 ppm in the ^{31}P spectrum is probably due to terminal $\text{P}(\text{OAl})_3\text{OH}$ sites at defects and the surface of the crystallites. The ^{31}P spectrum of the calcined and hydrated material (Figure 16) consists of two well-resolved resonances at −23.4 and −29.6 ppm in the intensity ratio of 1:4, which suggests that four of the five phosphorus sites have similar chemical shifts.

Figure 15 The structures of AlPO₄-5 and AlPO₄-11 viewed down the (001) axis

The development of double rotation (DOR), in which the sample is rotated around two different axes simultaneously and dynamic angle spinning (DAS), in which the sample is rotated sequentially about two different axes, was a major advance in the study of solids. DAS and DOR remove not only chemical shift anisotropy, but also second-order quadrupolar interactions.⁵⁶ ²⁷Al DOR distinguishes the distorted five-coordinate aluminum sites in the molecular sieve precursor AlPO₄-21. Upon calcination, AlPO₄-21 transforms to AlPO₄-25, which has two four-coordinate aluminum sites with similar isotropic chemical shifts. These cannot be resolved in an 11.7 T field, but are resolved by DOR at 4.2 T because of their different quadrupole coupling constants.

²⁷Al DOR was used⁵⁷ to monitor the nature of the phase transition of AlPO₄-11 observed when water is adsorbed. The DOR spectrum of hydrated AlPO₄-11 shows that the line at 30 ppm is indeed due to a single environment. However, the broad DOR peak from six-coordinate aluminum indicates the presence of a range of sites, suggesting that all five crystallographic sites are hydrated to a similar extent. The DOR spectrum of the dehydrated calcined sample shows only a single peak in the 11.7 T field, despite the fact that three crystallographic sites are present. This indicates that the three sites have similar chemical shifts.

13 VPI-5 AND AlPO₄-8

VPI-5 is a crystalline aluminophosphate molecular sieve containing 18-membered rings of aluminum and phosphorus

Figure 16 ²⁷Al and ³¹P MAS NMR spectra of 'as-prepared' and hydrated calcined AlPO₄-11 obtained in a 9.4 T field⁵⁷

atoms (Figure 17). The large (about 1.2 nm) channel diameter gives VPI-5 considerable potential for the separation of large molecules, and for catalytic cracking of the heavy fractions of petroleum. The material has thus been studied extensively. The room-temperature ³¹P MAS NMR spectrum of hydrated VPI-5 contains three peaks in an intensity ratio of 1:1:1 (Figure 18) and the ²⁷Al spectrum resonances from four- and six-coordinate aluminum. This is because 'as-prepared' VPI-5 is an aluminophosphate hydrate with three inequivalent sites for both phosphorus and aluminum: one of the aluminum sites is bonded to two chemisorbed water molecules, thus becoming six-coordinate. Variable temperature NMR^{58,59} (Figure 18) shows that VPI-5 undergoes a reversible phase transition to a higher symmetry structure with two ³¹P resonances in a 2:1 intensity ratio and two sites for both aluminum and phosphorus. The peaks at -23 ppm (1) and -27 ppm (2) were assigned to phosphorus atoms in 6-4 sites (P2 and P3), and the peak at -33 ppm (3) to P atoms in 4-4 sites (P1). ³¹P-³¹P spin diffusion spectra were used to establish how peaks 1 and 2 are to be assigned to particular P2 and P3 sites.⁶⁰ Each pair of ³¹P resonances gives rise to cross peaks (Figure 19) and the efficiency of spin diffusion (cross-peak intensity) decreases with increasing spinning rates. An analysis of the plot of cross-peak intensity versus the spinning rate in the light of interatomic distances known from the XRD structure showed that peaks 1, 2, and 3 should be assigned to sites P2, P3, and P1, respectively.

²⁷Al DOR spectra⁶¹ confirm that the peak from four-coordinate aluminum arises from two crystallographic sites, and the broad peak from six-coordinate aluminum from a single site. Although the two four-coordinate aluminum sites are not resolved by DOR at high fields because of their similar chemical shifts, they may be resolved at lower fields because the sites have different quadrupolar coupling constants.

Figure 17 One layer of the framework structure of hydrated VPI-5 taken from the stereoscopic view along the [001] direction showing the deviation from $P6_3cm$ symmetry.⁵⁹ Aluminum and phosphorus atoms are located at the apices of the polygons. Sites located between two fused four-membered rings are known as 4–4 sites; those located between six-membered and four-membered rings are known as 6–4 sites. P2 and P3, and Al2 and Al3 sites are inequivalent as a result of the distortion. The Al1 site is six-coordinate as a result of bonding to four bridging oxygen atoms and two ‘framework’ water molecules

Heating hydrated VPI-5 results in a transformation to $AlPO_4-8$. ^{27}Al DOR shows⁶¹ that in dehydrated VPI-5 there are also only two four-coordinate aluminum environments in the intensity ratio of 2:1. However, after a period during which the sample had been kept in a rotor which was not completely air-tight, many additional NMR resonances are found, corresponding to a partially rehydrated material (Figure 20).

Spin echo double resonance (SEDOR) allows the relative spatial disposition of spins to be deduced. By measuring the dipolar interaction between nuclei, which is inversely proportional to the cube of the internuclear distance, SEDOR probes only their immediate vicinity. ^{27}Al – ^{31}P SEDOR can measure Al–P distances in $AlPO_4$ materials.⁶² MAS NMR with dipolar dephasing has been used⁶³ for the study of mixed pairs of quadrupolar and spin- $\frac{1}{2}$ nuclei in VPI-5. Dipolar connectivities between ^{31}P and ^{27}Al were examined in both directions.

NMR spectra of $AlPO_4-8$ show single ^{31}P and ^{27}Al peaks and a small ^{31}P peak at -12.1 ppm.⁶⁴ In hydrated $AlPO_4-8$, about 34% of the aluminum is six-coordinate. The ^{31}P spectrum shows several environments, and at least five peaks are required for the simulation. The structure of dehydrated $AlPO_4-8$ calls five sites in the population ratio of 2:2:2:2:1.

14 SAPO MOLECULAR SIEVES

The general formula for a SAPO molecular sieve is $M_{(y-z)/n}[Si_xAl_yP_zO_2] \cdot wH_2O$, where $x + y + z = 1$, M is the charge-balancing cation, and the amount of silicon depends on the structure type. It is generally found that $y > z$, indicating that substitution of silicon into phosphorus sites is more frequent than substitution into aluminum sites. However, the aluminum content is often less than 50%, so that substitution of two silicon atoms for an Al + P pair must also occur. ^{29}Si NMR spectra of SAPO suffer from low signal-to-noise ratios due to the low concentration of silicon and the low natural abundance of ^{29}Si . The ^{29}Si chemical shift of SAPO-5 (isostructural with $AlPO_4-5$) is -92 ppm, which is slightly more negative than

Figure 18 Variable temperature ^{31}P MAS NMR spectra of hydrated VPI-5 in a closed rotor system⁵⁹

that for $Si(OAl)_4$ environments in zeolites, and it appears that the silicon is substituting exclusively onto the phosphorus sites of the framework. ^{27}Al , ^{31}P , and ^{29}Si NMR spectra⁶⁷ each contain single peaks, but some ^{29}Si spectra show peaks at -92 , -102 , and -108 ppm, indicating the presence of two or more silicon environments. The -102 ppm peak may originate from siliceous species on the surface of the crystallites. It also appears that, even allowing for the possible presence of amorphous silica, some regions are richer in silicon than are $Si(OAl)_4$ sites. Pairwise substitution of silicon onto aluminum and phosphorus sites seems to take place. The ^{31}P peak has the same chemical shift as in $AlPO_4-5$, which indicates that all phosphorus is in the $P(OAl)_4$ environment. Narrow ^{31}P NMR peaks from SAPO materials indicate that no Si–O–P bonds are present, and no case has yet been reported where all the silicon is present exclusively in $Si(OAl)_4$ environments.

The framework structure of SAPO-37 is that of the zeolite faujasite. There is a single ^{31}P peak at -26.4 ppm corresponding to $P(OAl)_4$ sites, and a single ^{29}Si peak at

Figure 19 Two-dimensional ^{31}P NMR spin diffusion spectra of hydrated VPI-5 recorded with MAS at 4.9, 6.5, and 10.1 kHz.⁶⁰ The three spectra are not on the same intensity scale, and so only the relative intensities within each can be compared

−90.2 ppm corresponding to $\text{Si}(\text{OAl})_4$ sites, indicating that the ideal silicon-for-phosphorus mechanism operates. Samples with high silicon content give more complicated ^{29}Si spectra, with features at −86, −90, −94, −98, −102, and −106 ppm.⁶⁸ The strongest of these, at −90 ppm, corresponds to the $\text{Si}(\text{OAl})_4$ units in pure SAPO materials, while the others correspond to $\text{Si}(\text{OAl})_x(\text{OSi})_{4-x}$ units in zeolite Y. This suggests that SAPO-37 may contain inhomogeneous growths of silicoaluminophosphate and aluminosilicate regions.

The structure of SAPO-34 is that of the zeolite chabazite. The single NMR peak of ^{29}Si at −92 ppm^{69,70} indicates that the exclusive substitution mechanism of silicon onto phosphorus sites applies, leading to the creation of Brønsted acid sites. ^{13}C MAS NMR spectra of SAPO-34 with adsorbed MeOH reveal hydrocarbon transformations upon heating the sample.⁶⁹ The major products are C_1 and C_2 organics; although formed, C_4 to C_6 hydrocarbons are too large to diffuse out through the eight-membered rings. The C_3 species are present in the product in a lower yield than expected, because the pore system is partially blocked by longer chain hydrocarbons.

15 MeAPO MOLECULAR SIEVES

The framework formula of a MeAPO sieve is $[\text{Me}_x\text{Al}_y\text{P}_z\text{O}_2]$, with $x + y + z = 1$, and $z = 0.5$, indicating that the

Figure 20 ^{27}Al NMR spectra of dehydrated and partially rehydrated VPI-5:⁶¹ (a) ^{27}Al MAS and (b) ^{27}Al DOR spectrum of dehydrated VPI-5; (c) DOR spectrum after 2 days of rehydration; (d) DOR spectrum after 23 days of rehydration

metal substitutes exclusively onto the aluminum sites of the equivalent AlPO_4 structure. MeAPOs can therefore contain Brønsted acid sites. Deviations from $z = 0.5$ are attributed to extraframework metal ($z < 0.5$) or phosphorus ($z > 0.5$). $x > 0.125$ implies the presence of $\text{Me}-\text{O}-\text{P}-\text{O}-\text{Me}$ bonds.

The ^{27}Al MAS NMR spectrum of MgAPO-20 containing 15% magnesium⁷¹ (Figure 21) shows a single $\text{Al}(\text{OP})_4$ environment, while the ^{31}P spectrum contains two major peaks at −21.1 and −28.0 ppm from $\text{P}(2\text{Al},2\text{Mg})$ and $\text{P}(3\text{Al},1\text{Mg})$ units in an intensity ratio of 1:2. The low intensity peaks come from $\text{P}(1\text{Al},3\text{Mg})$ and $\text{P}(4\text{Al})$ units. Magnesium is therefore present exclusively on aluminum sites, which makes it possible to calculate the framework composition from the intensities of the NMR peaks and to distinguish between possible ordering schemes for phosphorus, aluminum, and magnesium.

^{11}B spectra of BAPO-5 show that boron is four-coordinate, but is not necessarily a part of the framework. Only one ^{31}P peak is found, even though $\text{P}(\text{OAl})_3(\text{OB})$ sites are expected to be present. Similarly, there is no direct evidence for the presence of framework lithium in LiAPO-5 .

Figure 21 (a) ^{27}Al and (b) ^{31}P MAS NMR spectra of 'as-prepared' MgAPO-20⁷¹

16 ^2H NMR STUDIES OF MOTION IN MOLECULAR SIEVES

Since the quadrupolar interactions of ^2H are sensitive to molecular motion, the nucleus is useful for the study of molecular dynamics over a wide range of frequencies. Variable temperature studies of small organic molecules adsorbed on a series of zeolites⁷² provide information on the filling of the intracrystalline space, the motion of the adsorbed species and site-selective adsorption. The ^2H spectra of deuterated *p*-xylenes $\text{CH}_3\text{C}_6\text{D}_4\text{CH}_3$ and $\text{CD}_3\text{C}_6\text{H}_4\text{CD}_3$ on zeolite Na-ZSM-5 in terms of possible dynamic states and sorption sites of the guest molecules identify five dynamic states, the relative populations varying with the level of loading and the

temperature.⁷³ ^2H NMR results on *p*-xylene- d_6 , toluene- d_3 and benzene- d_6 adsorbed on H-ZSM-5,⁷⁴ as well as on mono-, di-, and trimethylamine on zeolites ZK-5 and Y⁷⁵ yield a wealth of dynamic information.

Examination of the dynamic behavior of water in the channels of VPI-5 leads to a motional model which applies in the temperature range 225–348 K.^{76,77} There are at least two sites for the intracrystalline water: one is bound to framework aluminum, and undergoes rotational motion about the Al–OH₂ bond, the other is a free site within the VPI-5 channels. The motion in this site is approximately isotropic, and the tumbling rate increases with temperature. The dynamic behavior of water in the temperature range 261–297 K is rather unexpected.

Multiple quantum (MQ) NMR, a 'spin counting' tool for homonuclear spin clusters,⁷⁸ is also suitable for the study of species adsorbed in molecular sieves.^{79,80} Nuclear spins are forced to act collectively via their dipolar couplings, and the resulting multiple quantum coherences are detected after conversion into observable single quantum coherences. If the system constitutes a collection of isolated clusters, the multiple quantum count reaches a plateau corresponding to the number of spins in the cluster. Figure 22 shows the results of ^1H MQ NMR experiments for hexamethylbenzene, a molecule containing 18 hydrogen atoms, adsorbed on zeolite Na-Y.⁷⁹ At lower loadings the plateau corresponds to about

Figure 22 Results of ^1H MQ NMR experiments for hexamethylbenzene adsorbed at 573 K on dehydrated zeolite Na-Y⁷⁹

one hexamethylbenzene molecule per supercage, and at higher loading to two molecules per supercage.

1 INTRODUCTION

Zeolites are crystalline aluminosilicates composed of tetrahedra of oxygen anions which surround either a Si^{4+} or Al^{3+} cation. These tetrahedra are arranged such that each oxygen is shared by a neighboring aluminum or silicon atom. Due to an overall stoichiometry of two oxygen anions per tetrahedral center, a net charge of -1 accrues for each aluminum in the zeolite lattice. This negative charge is compensated for by a cation, most commonly a proton or a metal ion of Group IA or IIA. The nature of the cation influences the strength of the acid/base properties of the zeolite.

A great deal of the interest in zeolites stems from the strong Brønsted acidity of the hydrogen forms. Two very important processes are currently carried out over acidic zeolites, the cracking of petroleum and the conversion of methanol to gasolines (MTG process). Petroleum cracking is carried out over hydrogen forms of the faujasite zeolite Y, a medium-pore zeolite comprised of cages with a 1300 pm diameter. Access to these cages is provided by tetrahedrally arranged windows having diameters of 740 pm. Much of the NMR work dealing with the chemistry of olefins is, in part, motivated by the need for a better understanding of the mechanisms of petroleum cracking. The MTG process provides an alternative source of gasoline from methanol, which can be obtained from synthesis gas, itself a product of coal gasification. The MTG process is a relatively recent discovery.^{1,2} It is carried out over the acidic form of the zeolite ZSM-5, a pentasil zeolite having two types of slightly elliptical intersecting channels, one straight and the other sinusoidal. The channel cross-sections are 530 pm by 560 pm and 510 pm by 550 pm respectively. Where the channels intersect a larger void region results.

While both of the above catalytic processes rely on the acidic nature of the zeolites involved, they are also facilitated by the molecular sieving properties of the zeolites. The size and shape of the channels and cages leads to several types of shape selectivity, reactant selectivity, product selectivity, and selectivity caused by restriction at the active site of catalysis.

Most NMR studies of reactions in zeolites have involved the reactions of olefins or alcohols. A prime concern has been the manner in which the acid (or base) properties of the zeolites affect the intermediates and products of these reactions. Shape-selective aspects of the catalysis, particularly those relating to the MTG process, have also been intensely

studied by NMR. With time, olefin and alcohol reactions are accompanied by coking of the catalyst. The formation of coke deposits during reaction has been the focus of several NMR studies. This review will focus primarily on these areas. NMR studies dealing strictly with adsorption into zeolites will not be addressed in this article.

2 REACTIONS OF OLEFINS

While many techniques can be applied to study product distributions over catalysts, very few have the capability of probing the chemistry within a zeolite catalyst. Such internal monitoring provides direct evidence for shape selectivity as well as information on the nature of the adsorbed intermediates in a chemical process. NMR is becoming a very powerful tool for obtaining this type of information.

One of the earliest studies of olefin reactions in zeolites involved low-resolution ^{13}C NMR spectra of ethylene reacting over H-ZSM-5.³ At room temperature immobile polymeric paraffins were evident. When water was added, and the sample heated to 573 K, lighter olefins and paraffins were observed as a product of cracking of the polymeric material.

Van den Berg et al.⁴ applied ^{13}C NMR to the study of a number of adsorbed olefins on H-ZSM-5. These authors adsorbed ethylene, propene, isobutene, and 2-methyl-1-butene at room temperature. The ^{13}C NMR spectra revealed that at 300 K a majority of linear oligomers were formed over the catalyst for all of the adsorbates studied. The average chain length decreased in the series $\text{C}_2\text{H}_4 \gg \text{C}_3\text{H}_6 > i\text{-C}_4\text{H}_8 > 2\text{-methyl-1-butene}$. Some small amounts of branched hydrocarbons were observed with ethylene and isobutene. When ethylene was adsorbed into H-ZSM-5 at 373 K a significant amount of branching occurred and the average chain length decreased. When this reaction was performed over H-mordenite the products were highly branched. The formation of primarily linear chains in H-ZSM-5 was attributed to restrictions due to the pore dimensions. The authors proposed that branched oligomers originally formed at channel intersections and were then linearized through isomerization reactions. The larger pores of the mordenite allowed for branched species.

Zardkoohi et al.⁵ studied the reaction of propene labeled with ^{13}C at the 2-site over both normal and ultrastable ($\text{Si}/\text{Al} = 4$) H-Y zeolite. In this work it was assumed that carbons scrambled via a cyclopropane intermediate prior to oligomerization. Cross polarization with magic angle spinning (CP MAS) was used to acquire the spectra. A peak at 250 ppm was assigned to formation of a carbenium ion $\text{CH}_3\text{C}^+\text{HCH}_3$. Olah's work⁶ with superacids had shown that stationary secondary carbocations should resonate between 300 and 330 ppm. The carbenium ion proposed in this work interacts with zeolitic oxygen, and, because of the typical 80 ppm shift to low frequency (upfield) of oxygenated species such as RC^+OH relative to RC^+R moieties, the shift of 250 ppm was deemed a reasonable one for such a species. The methyl groups associated with the isopropyl cation should resonate at 48 ppm, but this area was obscured by peaks due to oligomers. The authors proposed the following mechanism (Scheme 1):

A peak at 160 ppm was assigned to a dynamic equilibrium between carbons in an ethyl isopropyl carbenium ion and a methyl isobutyl carbenium ion. This resonance position is an

Scheme 1

average of a resonance at 330 ppm due to the carbenium ion and one at 60 ppm due to the methylene. The average value of 195 is consistent with the observed value of 160 ppm if one again considers the low-frequency shift induced by the framework oxygen. A peak also appeared at 70 ppm which was assigned to the carbon at the β position relative to the carbenium center.

Intense peaks at 40 ppm and 30 ppm were assigned to methylene and methyl groups respectively from oligomeric species and carbocations. The intensity of these peaks was higher in H-Y than in the ultrastable H-Y sample due to the blocking of pores by detrital aluminum species in the ultrastable H-Y.

In later work by this group⁷ an apparatus called CAVERN (cryogenic adsorption vessel enabling rotor nestling) was employed for adsorption studies. Propene samples labeled at the 1-, 2-, and 3-positions gave different spectra on H-Y. As a result, label scrambling was not present as had been presumed in their previous study. When [2-¹³C]propene was adsorbed, signals were observed at 250, 143, and 87 ppm. Both single pulse Bloch decays and CP MAS spectra were employed in this study. Signals in the aliphatic region and those of unreacted propene had T_1 values of approximately 80 ms, while the peak at 87 ppm had a T_1 of 2–3 s. The short T_1 values indicated mobile species while the longer T_1 was indicative of a more strongly bound species. In experiments of this type Bloch decays are more quantitative, since they do not depend upon efficiency of magnetization transfer between carbons and protons. In the Bloch decays the size of the signal at 87 ppm was greatly reduced, comprising only about 2% of the spectral intensity. Carbon-13 $T_{1\rho}$ values were equal to 5–10 ms for all species. The CAVERN was loaded and spectra were recorded at temperatures from 213 to 293 K. At 213 K very little propene had reacted. At 253 K the oligomer peak appeared. At 263 K about one-third of the propene had reacted and peaks at 87 and 140 ppm were now evident. At 273 K there was 70% conversion with increasing intensity at 87 and 140 ppm.

The peak at 87 ppm had been previously assigned to those carbons adjacent to the nonequilibrating carbenium ions, which resonated at 250 ppm. However, there was no peak observed at 250 ppm in this series of spectra; therefore, the assignment of the peak at 87 ppm to carbons adjacent to the cation had to be abandoned. A reasonable alternative explanation was to assign the resonance to an alkoxy (alkyl silyl ether) species bound to a zeolite lattice oxygen atom. The peak at 140 ppm was assigned to olefinic carbon atoms of oligomeric species. At room temperature there was complete conversion, and a peak at 250 ppm appeared, which was assigned to a carbocation. When 1-propene was used, two major changes were exhibited: no peak at 87 ppm was observed and, secondly, the aliphatic region extended further to low frequency (indicating a greater contribution of methyl groups). Thus, the carbon atoms in the 1-position ended up in more methyl groups than carbon

Scheme 2

atoms at the 2-position. No scrambling of label was observed. The authors proposed the following mechanism (Scheme 2) to explain these observations:

Upon adsorption, propene forms an alkoxy species. This is followed by Markovnikov addition of a second propene prior to cleavage of the alkoxy. A third propene adds, followed by cleavage, to form a disubstituted olefin. Probable rearrangement of the olefin to more stable olefins occurs in the acidic environment of the zeolite.

This mechanism relied heavily on the assignment of the peak at 87 ppm to the alkoxy. To support this assignment the authors noted that the intensity of this peak did not correlate at all with the peak at 250 ppm assigned to the carbocation. Also, upon exposure of the sample to moisture, there was a loss of intensity of the resonance at 87 ppm and formation of a peak at 67 ppm. A peak at 67 ppm is consistent with secondary ethers or alcohols having the hydroxyl group in the 2-position, but not from primary or tertiary alcohols. The expected product from the alkoxy would be an alcohol with the hydroxyl group in the 2-position. The peak at 67 ppm survived interrupted decoupling of 50 μ s, while that at 87 ppm did not. This suggested that the species resonating at 87 ppm was an immobilized, protonated carbon. The peak at 87 ppm was never observed with 1- or 3-propene. This finding rules out a long-lived carbocation which would surely scramble. The shift of this peak was about 20 ppm to high frequency from that expected for an alkyl silyl ether. However the presence of a nearby Al atom and the incipient carbocation nature of the species may explain the high-frequency shift. Low-temperature experiments confirmed that propene itself was mobile in the zeolite at low temperatures and could diffuse to form alkoxy intermediates.

The assignment of the peak at 250 ppm to a nonequilibrating carbocation, is now believed to be incorrect. The interaction between the carbocation and the zeolitic oxygen atom is apparently so strong that an alkoxy is formed. For a long-lived carbocation to exist in the zeolite it cannot interact with an oxygen atom and must be stabilized in some way. The authors suggested that olefins are formed, and then undergo hydride abstraction and cyclization, as is observed in the conjunct polymerization of alkenes. In this process alkanes are formed at the expense of hydrogen from the olefins, which in turn are converted into alkyl cyclopentenyl cations. The proposed cations contain carbons that should resonate at 249 and 158 ppm.^{8,9} If this assignment is correct there should be a correlation between intensity at 158 ppm and 250 ppm. Careful examination of their spectra show this to be the case. The peaks appear at a roughly 2:1 intensity ratio as expected. The same alkoxy intermediate was observed by Aronson et al.¹⁰ (see below) upon adsorption of 2-methyl-2-propanol on HZSM-5.

Later work by the Haw group¹¹ involved studies of samples prepared at 298 K by adsorbing both 1- and 2-labeled propene. The samples were then heated in situ to 503 K. After heating, the low-frequency region showed many highly resolved resonances indicative of small mobile species. Resonance shifts and J couplings allowed the identification of isopentane, isobutane, 2,3-dimethylbutane, and propane. The high-temperature spectra of 1- and 2-labeled samples are identical, indicating scrambling of the labels. This is consistent with carbocation mechanisms proposed for high-temperature cracking reactions.¹² The hydrogen necessary for formation of the alkanes from the olefins comes about by coke formation. Coke is observed by CP MAS as a peak between 120 and 140 ppm.

The alkylation of isobutane with 1-butene in LaNaY zeolite was studied by ^{13}C CP MAS NMR.¹³ During the initial feed, all of the butene was consumed and the products were comprised primarily of a mixture of isoalkanes. In the second stage the butene conversion dropped to about 40% and the product distribution changed drastically to isoalkenes, indicating that in the early portion of the reaction the isobutane was being alkylated by the olefin. In the latter stage, however, the olefin was oligomerizing. At higher temperatures the product distributions shifted to lower molecular weights as a result of more pronounced contributions from cracking reactions. Above 220 °C aromatics began to appear.

Butadiene reactions on H-Y and H-ZSM-5 were studied by ^{13}C MAS NMR.¹⁴ Bloch decays were used to probe mobile species whereas CP MAS was used for immobile molecules. Butadiene oligomerizes by primarily 1,4-addition upon adsorption on H-ZSM-5. 1,4-Addition accounts for most of the oligomer in H-Y as well, although 1,2-addition was a minor contributor. As the reaction proceeded there was a loss of intensity in the olefinic region and a corresponding increase in the aliphatic region due to cyclization. These subsequent reactions were zeolite-dependent. In H-Y the linear product underwent cyclization to form fused rings, while isolated rings were formed in H-ZSM-5. Branching reactions and 1,2-enchainment resulted in oligomers with a large methyl group content in H-Y. The 1,4-addition reactions, followed by cyclization, result in pore blockage and catalyst deactivation. No reactive intermediates or carbenium ions were observed.

The Haw group¹⁵ adsorbed acetylene on H-Y and HZSM-5 zeolite. At room temperature no reaction was observed. Upon heating to 473 K, however, two major resonances appeared under CP MAS conditions at 143 and 107 ppm, along with peaks from aliphatic and aromatic carbons (tar). The fact that these reactions were not occurring in the gas phase was confirmed by attempting the reaction over NaY. The authors suggested the species analogous to those observed by Chin and Ellis¹⁶ on alumina (1). Reaction of this sample with water in

the atmosphere produced acetaldehyde. Further heating in atmosphere eventually resulted in acetic acid. Control experiments involving acetylene and water produced tars with a highly paraffinic nature. The hydrogen source for these tars appears to be water. In fact, the amount of tar formed could

be correlated with the degree of hydration of the zeolite. Interrupted decoupling experiments at low and high temperature indicated that the adsorbed species probably undergoes rotation about its O-C bond at 298 K.

The reaction of ethylene over a series of cocation-exchanged Ru-Y zeolites was studied.¹⁷ At room temperature ethylene was converted to ethane and butane on the timescale of days. 2-Butenes appear to be intermediates in the reaction. Coadsorption of hydrogen led to an increase in the initial rate, which was roughly first order with respect to hydrogen. The rate of reaction of ethylene was strongly dependent upon the cocation in the order $\text{Ru-H-Y} > \text{Ru-Ca-Y} > \text{Ru-NaY}$. At intermediate temperatures isomerization of butane to isobutane occurred presumably at acid sites. Above 623 K, carbon-carbon bond cleavage caused methane to be the only detectable product.

Methyl halides were found to convert to hydrocarbons over a large number of faujasite zeolites.¹⁸ Upon adsorption of methyl iodide onto Cs-X a zeolite-bound methoxy species was formed. This species appears at 58 ppm. The assignment of this resonance was proven unequivocally by several NMR methods, including interrupted decoupling, slow MAS, and rotational resonance. Chemical verification was achieved by interacting the adsorbate with water to produce the corresponding alcohol. Ethyl iodide forms the corresponding framework-bound ethoxy species with resonances at 68 and 17 ppm. These peaks also passed all of the criteria for assignment to framework-bound species.

At higher temperatures, both the surface methoxy and the surface ethoxy groups were converted to ethylene, and subsequently to aliphatic moieties. Ethylene did not convert to aliphatic species in the absence of the alkyl iodides over these catalysts. Evidently this conversion of ethylene to aliphatics was catalyzed by HI which was released upon formation of the alkoxy from the alkyl halide.

Methyl chloride and methyl bromide also react in an analogous manner to methyl iodide; however, the concentration of methoxy groups and the reactivity to hydrocarbon synthesis was in the order $\text{CH}_3\text{I} > \text{CH}_3\text{Br} > \text{CH}_3\text{Cl}$. This order of reactivity is as expected for $\text{S}_{\text{N}}2$ reactions based upon the leaving group ability. One may consider the reaction of methyl halide with the zeolite as attack on the carbon by the nucleophilic oxygen atom of the zeolite lattice, resulting in displacement of the halogen. The basicity of a zeolite increases with the size of the cation. The activity of this reaction should, therefore, increase with increasing size of the cation.

The effect of cation nature on the reaction was investigated. Different cations affected both the activity and the selectivity of the catalysts. NaX was the most active, while K-X and Rb-X were less active than Cs-X. H-X was very unreactive, indicating that activity is not due to acidity. With the exception of NaX, the activities were in line with those predicted by consideration of zeolite basicity. Rb-X was unique in that it showed a high selectivity for olefin and aromatic products. Small shifts in the methyl resonance as a function of the cation were observed. These shifts correlated with activity of the catalyst: the higher the resonance frequency, the more active the catalyst. Cesium-133 NMR showed that the adsorbates interact with the cation sites and that this interaction may be significant in affecting catalyst activity. The framework also affected catalyst activity in the order $\text{Cs-X} > \text{Cs-Y} > \text{Cs-ZSM-5}$.

3 REACTIONS OF ALCOHOLS

NMR has been used extensively to investigate the mechanism of formation of the first carbon–carbon bond in the MTG process. Direct evidence for two types of shape selectivity have been revealed by NMR: product selectivity and active site selectivity.

A study of methanol and ethanol conversion over H–ZSM-5 was undertaken using ^{13}C NMR without MAS.¹⁹ The NMR results were compared with those from gas chromatography. Below 250 °C there was nearly complete conversion of methanol to dimethyl ether. When the temperature was raised to 300 °C there was a loss of intensity in the ether range and an increase in $-\text{CH}_2-$ and $-\text{CH}_3$ resonances. With increasing temperature these peaks shifted to high frequency, indicative of formation of branched chains on aromatic residues. The aliphatic to aromatic ratio of the initially low-temperature adsorbed methanol was 5:1, while a fresh dose of methanol converted directly at 350 °C yielded a ratio of 2:1. It therefore appears that there is competition between aliphatic and aromatic product, rather than a sequential change from aliphatic to aromatic moieties.

Ethanol adsorption at 150 °C yielded diethyl ether. Between 150 and 250 °C an olefinic peak appeared and was assigned to ethylene. Above 250 °C the olefinic peak diminished and an aliphatic resonance formed between 14 and 23 ppm. No distinct aromatic peaks were visible. The authors proposed mechanisms involving carbenium ions.

Carbon-13 NMR studies of methanol on a germanic, near-faujasite zeolite²⁰ showed that methanol reversibly yielded dimethyl ether. Greater conversion occurred at higher temperatures. No other products were observed on the faujasite. Following prolonged heating at 300 °C, a broader resonance appeared underneath that for dimethyl ether (DME) near 60 ppm. This peak was attributed to surface methoxy formation. Peaks due to aldehydes were observed at 193 ppm during reaction of methanol on H–ZSM-5 in the presence of CO.²¹ It was proposed that this signal derives from incorporation of CO via a carbenium ion mechanism.

Carbon-13 CP MAS NMR was used to study the carbonaceous residues formed in H–ZSM-5 and H–mordenite from methanol and ethylene.²² Methanol on H–ZSM-5 yielded a broad distribution of aliphatics including propene, propane, *n*-butane, isobutane, and isopentane. In the aromatic region there was some evidence of benzene, toluene, and xylenes. Over mordenite a much narrower aliphatic product distribution was obtained: only propane, propene, and *n*-butane. The aromatic distribution was, however, broader and included fused aromatics. On both catalysts, surface methoxides were suggested as intermediates. Isoparaffins were more prevalent than linear ones on H–ZSM-5, while on mordenite isoparaffins and C_5 -aliphatics were not seen. Instead, the larger pores of mordenite allowed conversion of C_4 – C_6 olefins into aromatics by mechanisms similar to conjunct polymerization.

Ethylene formed linear chains on H–ZSM-5. The average chain length was 10–12 carbon atoms. Steam cracking of this sample resulted in a large number of C_5 and C_6 residues and some alkylation, as evidenced by the appearance of ethylbenzene. When an ethylene-loaded sample was heated to 573 K in the presence of water, products included the linear paraffins (propane and butane), branched paraffins (isobutane and isopentane), and aromatics (toluene, xylene,

and ethylbenzene). Unlike in the steam-cracked catalyst, xylenes were quite abundant, indicating that they are formed by the conjunct polymerization of olefins.

Kotanigawa et al.²³ studied the adsorption and reaction of methanol on H–Y zeolite by ^{13}C NMR. At room temperature a signal from adsorbed methanol was observed at 48.9 ppm. When the sample was heated to 220 °C four peaks appeared, one of which was derived from the adsorbed methanol. A peak at 59.2 ppm was assigned to a surface methoxyl; however, later work by Anderson and Klinowski²⁴ suggests that this peak was probably due to DME. The two other resonances at 27.2 and 64.7 ppm were tentatively assigned to the methyl carbon of 2-propanol and carbons adjacent to oxygen (either the 2-carbon of 2-propanol or the carbon of a hydroxymethyl group) respectively. Higher temperatures produced surface alcohols as well as a resonance which these authors assigned to a surface epoxy based upon IR data. When 480 °C was reached, olefins were observed. Based upon these assignments the authors proposed that the formation of the first carbon–carbon bond involves a surface methoxyl reacting with a hydroxymethyl group via a carbenium ion intermediate.

Aronson et al.¹⁰ studied the 1:1 adsorption complex of 2-methyl-2-propanol with a Brønsted site on H–ZSM-5. The 2-methylpropanol was labeled at the hydroxyl carbon. Under the conditions of the experiment the adsorbate was dehydrated and the water which was formed desorbed completely, as verified by temperature-programmed desorption (TPD) and thermogravimetric analysis (TGA). Two broad features appeared in the Bloch decay ^{13}C spectra at 80 and 30 ppm in the ratio of 2:3. The peak at 30 ppm indicated that some additional reaction had occurred changing the hydroxyl carbon to an aliphatic one, probably through oligomerization. No peak in the area of 330 ppm was seen, thereby ruling out a carbenium ion resonating in the area reported by Olah.⁶ Furthermore, no line shifts were evident with changes in temperature, thereby ruling out exchange. A small resonance at 123 ppm from carbon–carbon double bonds was observed. Heating of this sample to 373 K resulted in an increase in the intensity and complexity of the aliphatic region. There was a compensatory decrease in the intensity in the 80 ppm region associated with carbons attached to oxygen. Most of the oligomers were still attached to the zeolite in alkyl silyl ethers, since the intensity in the region above 100 ppm remained low. The peak near 80 ppm exhibited an axially symmetric powder pattern with $\sigma_{\parallel} = 93$ and $\sigma_{\perp} = 44$ ppm at 200 K. The isotropic shift was slightly to high frequency from that of the 72.6 ppm shift of the *tert*-butoxide group in bis[(2-ethylhexyl)oxy]di-*tert*-butoxysilane, but to low frequency from the *tert*-butoxide group attached to the more electropositive Ti atom in $\text{Ti}(t\text{-BuO})_4$.²⁵ The authors presented a carbenium ion-mediated scheme for formation of some olefinic carbons as well as oligomers (Scheme 3).

The complexity of the spectra in the aliphatic region could not be explained by their scheme. In particular, the appearance of a well-resolved peak at 13 ppm indicates that the labeled carbon has been converted into methyl or methylene groups. This implies rearrangement of tertiary carbenium ions.

From a combination of their TPD–TGA, IR, and NMR work, a potential energy surface was constructed. Reaction proceeds by protonation of the alcohol to form the oxonium ion. This dehydrates to form the alkyl silyl ether via the

Scheme 3

carbenium ion intermediate. The reaction proceeds again through the carbenium ion to the olefin product.

Anderson and Klinowski^{24,26} studied the adsorption and reaction of methanol in H-ZSM-5 zeolite. At room temperature a signal at 50 ppm was observed from adsorbed methanol. Higher pressures of methanol resulted in a second peak due to either vapor or methanol on the outer surfaces of the zeolite. Following heating at 150 °C for 5 or 20 min a resonance at 60 ppm attributable to dimethyl ether appeared. The authors showed via ¹H NMR that this occurs through interaction of the methanol with an acid site in the zeolite. The hydroxyl resonance was shifted to higher frequency by 7.9 ppm upon adsorption, due to formation of a methoxonium ion hydrogen bonded in the intracrystalline space. At larger coverages protonated clusters were formed.^{27,28} The ratio of DME/MeOH was constant with time, indicating that an equilibrium was attained. After treatment of the methanol-loaded sample for longer than 20 min at 150 °C a new resonance appeared at 184 ppm which could be identified as CO. CO was also produced at 250 °C. The production of CO from DME by two different mechanisms has been reported.^{29,30} Both mechanisms, however, involve formation of methane, which was not observed coincident with the formation of CO. CO is formed on ZSM-5 from methanol through a formaldehyde intermediate.³¹

After heating a methanol-treated sample at 250 °C for 54 min and then at 300 °C for 10 min, aliphatic resonances began to appear with a corresponding drop in the DME/MeOH ratio. It would seem that the higher hydrocarbons are either formed preferentially from DME and their formation occurs quicker than the reestablishment of equilibrium between DME and MeOH, or the equilibrium between DME and MeOH (which involves water) is affected by subsequent dehydration reactions. Further heating at this temperature caused complete conversion of methanol and DME to aliphatics and aromatics. Two narrow peaks due to mobile methane and cyclopropane were observed under Bloch decays, but not under CP. Despite spectral overlap, under MAS conditions a large number of products were readily identified, due to the multiplicity of resonances associated with most products. Because CO formed prior to hydrocarbon formation, and its resonant intensity decreased upon formation of hydrocarbon products, the authors suggested that CO was an intermediate in hydrocarbon formation. This was proposed to occur by hydrocarbonylation to ethanol at an iron impurity site, followed by dehydration of ethanol to ethylene. The authors were able to obtain ethylene as the primary olefinic product from an Fe³⁺-exchanged catalyst in support of this suggestion. Haw's group³² tested this hypothesis by carrying out the reaction of methanol over H-ZSM-5 in the presence of CO generated

from formic acid. Carbon-13 from CO was not incorporated in the product hydrocarbon. CO also did not catalyze the reaction of methanol to hydrocarbon as had been suggested by Jackson and Bertsch.³³

An examination of the aromatic region of the NMR spectrum following the 300 °C treatment revealed that the distribution of the adsorbed species during methanol conversion was very different from the product distribution. Product distribution data suggested that primarily *m*- and *p*-xylene, toluene and 1,2,4-trimethylbenzene would be found. The major species found by NMR in the adsorbed phase were, however, *o*- and *p*-xylene and 1,2,4,5-tetramethylbenzene, with smaller amounts of other species including some trimethylbenzenes. These trimethyl species were found in their equilibrium distribution³⁴ in the adsorbed phase, but the larger 1,2,3- and 1,3,5-forms were not found in the product distribution. This was a clearcut example of product selectivity. In ZSM-5 the channel dimensions are 560 × 530 pm; however, more space is available at channel intersections. The larger 1,2,3- and 1,2,5-forms must isomerize to the smaller 1,2,4-form in order to diffuse out of the zeolite. All four tetramethylbenzenes were observed in the catalyst, having been formed at channel intersections. They were not found in the product, again showing product selectivity. The tetramethylbenzenes were not formed in their equilibrium distributions, showing active site selectivity.

At 300 °C signals from the aliphatic region came predominantly from isobutane and propane. Large signals were also observed, however, from *n*-butane, *n*-hexane, *n*-heptane, isopentane, and methane. At 370 °C the number of straight-chain alkanes decreased and larger numbers of branched alkanes were evident. At higher temperatures many larger species were observed in the product distributions due to the larger channel dimensions which allowed diffusion out of the catalyst.

This group also studied methanol adsorption on SAPO-5 and H-ZSM-5 in order to determine the nature of the strong bonding of methanol to Brønsted sites in the zeolites and the conversion of methanol to DME.³⁵ On SAPO-5 at room temperature only mobile methanol was observed. Heating to 150 °C resulted in conversion of about one-third of the methanol to dimethyl ether which was still mobile. Further heating at 250 °C produced two species: methanol and another species exhibiting chemical shift anisotropy due to reduced mobility. The chemical shift suggested either a surface methoxyl or possibly immobile dimethyl ether.³⁶ Heating the sample above 300 °C produced mobile alkenes and aliphatic compounds. By contrast in H-ZSM-5 methanol adsorbed as methanol, but hydrogen bonded to a Brønsted site. The resonance shift remained at 50 ppm in the ¹³C spectra, but the ¹H spectra revealed a hydroxyl resonance near 9.4 ppm. When one methanol was adsorbed per Brønsted site there was considerable line broadening indicating strong bonding. The shift indicated that methanol was still intact. Thus, in H-ZSM-5 methanol strongly adsorbs by hydrogen bonding prior to dehydration, while on SAPO-5 the dehydration precedes the strong binding to the surface. This strong bonding pursuant to dehydration is followed by formation of the C-C bond.

Two-dimensional (2D) *J*-resolved spectroscopy was used to unravel the product distribution of a sample of H-ZSM-5 reacted with methanol for 30 min at 300 °C.³⁷ From the 2D spectrum the authors were able to show that the resonance at 22 ppm had a contribution from the methyl resonance of

isopentane. In later work using 2D spin diffusion NMR³⁸ they showed that this resonance also contained intensity from carbon atoms adjacent to methyl groups in *n*-hexane and *n*-heptane. This work showed the power of 2D techniques in the solid to resolve the many lines in the aliphatic regions of a working MTG catalyst.

Methanol conversion was also studied over SAPO-34.³⁹ The authors discovered an interesting shape selectivity in the chabazite-like structure. At 300 °C treatments many aliphatics up to C₆ were in abundance on the catalyst. This included branched hydrocarbons. Only C₃ and smaller species were present in anything but trace amounts in the product stream, however. Due to the small 380 pm windows to the cages, two types of shape selectivity occur. C₁ and C₂ molecules have unrestricted diffusion. C₃ species are somewhat restricted by occluded hydrocarbons, and C₄ and larger species are diffusion-restricted.

The question of the formation of the first carbon-carbon bond in the MTG process has been a source of great interest. In order to test the hypothesis that the trimethoxonium ion (derived from dimethyl ether) may play a role, trimethyloxonium salts were cation-exchanged into ZSM-5 and the ¹³C NMR spectrum was recorded under CP MAS conditions as a function of time.⁴⁰ The methyl groups of the trimethyloxonium ion resonated at 80 ppm. This signal gradually converted to two overlapping signals at 60 ppm which the authors attributed to surface methoxyl and dimethyl ether. Munson and Haw⁴¹ adsorbed DME on H-ZSM-5. At 293 K a resonance appeared at 80 ppm which could be assigned to the trimethoxonium ion. This species was generated from two dimethyl ether molecules and formed in a 1:1 ratio with methanol. This species could not be seen in methanol adsorption studies due to the shift in the equilibrium toward DME. At high temperatures DME yielded similar products as adsorbed methanol. The observation of this species in H-ZSM-5, while not proving that it is a reaction intermediate, lends some credibility to the Chang mechanism involving deprotonation of the trimethoxonium ion to form the methylenedimethyloxonium ylide.⁴²

A comparison of methanol conversion on straight channel offretites and increasingly tortuous erionite-like zeolites was undertaken.⁴³ The most fault-free (least tortuous) zeolite showed a proclivity for formation of long-chain polymeric hydrocarbons, which were highly branched. A chemical shift at 46 ppm due to tertiary carbons, and a peak at 58 ppm due to quaternary carbons were seen. Formation of these polymeric species was inhibited by the presence of only a few blockages in the channel structure. Channel tortuosity is, therefore, necessary to maintain selectivity to low olefins.

4 COKING

Richardson and Haw⁴⁴ coked samples with a single feed of butadiene at six different temperatures for 1 h. Carbon-13 NMR spectra generally showed two peaks, one due to aliphatics and one due to aromatic and olefinic resonances. The relative size of the aromatic peak increased drastically with treatment temperature. Over 90% of the NMR intensity observed from samples treated above 400 °C was attributed to aromatic species. A sample was heated under butadiene at 150 °C and then subjected to chemical extraction techniques. Virtually all of the coke was unrecoverable, indicating that

the coke comprised large, insoluble, high molecular weight species. Interrupted decoupling experiments confirmed that few carbons were protonated. This result suggests that cross polarization may not be quantitative. Spin counting experiments confirmed that at 150 °C about 80% of the carbon was observable, but that at higher temperatures a significant fraction of the carbon in the coked samples was unobservable.

A number of rare-earth-exchanged zeolites were investigated by CP MAS NMR and relaxation analysis.⁴⁵ Cross polarization was not greatly affected by diamagnetic La³⁺ or those ions having short electron *T*₁ values, including Nd³⁺ and Pr³⁺. For Gd³⁺- and Dy³⁺-exchanged zeolites the ¹H *T*_{1ρ} was drastically decreased, allowing insufficient time for cross polarization. This prevents quantifying coking reactions in these zeolites by CP MAS NMR. The effect was localized. As a result, dilution of the ion concentration in the zeolite allowed spectra to be obtained.

1 INTRODUCTION

Silica (SiO_2) is one of the most abundant materials on Earth.¹ If the wide range of silicate minerals in which silica 'formally' occurs is included, one can account for more than 60% of the Earth's crust in terms of silica. From the industrial point of view, the number of applications of silica is enormous, and we make no attempt to represent them all here. These technological applications of silica include its use in separations (e.g. column chromatography), in composite materials, in consumer products (e.g. as thickening agents), in immobilized reagents (e.g. heterogeneous catalysts), and even in foods. Although a variety of high-surface-area forms of silica are important, including precipitated and fumed silicas, in this article we will focus mainly on samples originating as *silica gels*, i.e. silica samples precipitated from the products of reactions such as:

The materials prepared in this manner tend to have high surface areas and high porosities, although these properties depend substantially on details of the preparation conditions. Most of the technologically important properties of silica depend substantially on the characteristics of the silica *surface*, e.g. the numbers, types, distributions, and reactivities of silanols, i.e. Si-OH groups, at the silica surface.

A priori, it would appear that the spin- $\frac{1}{2}$ nuclides ^{29}Si (4.7% natural abundance) and ^1H ($\sim 100\%$ natural abundance) should be useful for characterizing the silica surface, and possibly also the quadrupolar nuclides ^{17}O ($I = \frac{5}{2}$, 0.04% natural abundance) and ^2H ($I = 1$, 0.02% natural abundance). Clearly, for these quadrupolar nuclides to be useful, isotopic enrichment is required, but that has not been a major difficulty. Indeed, there has been a great deal of NMR work done on silicas and silica-based systems,²⁻⁵ and it would be impossible to review it all comprehensively here, because of reasonable space limitations. Furthermore, because of restrictions on space, it will not be possible to list all of the worthwhile studies in this research area. For these reasons, the convenient approach of emphasizing studies from our own laboratory is adopted, with apologies to those who feel their work may have been neglected.

2 NMR STRATEGIES FOR SILICA SURFACE SELECTIVITY

2.1 The Need

With any NMR experiment on a solid, a technique that provides no major detection advantage to nuclei at the surface will generate spectra that are dominated by peaks due to nuclei that are in positions in the interior (bulk) of a particle, because the number of nuclei that constitute the bulk of a particle will typically be much larger than the number of corresponding nuclei in analogous structural sites at the surface (unless the surface area is very large, say, $\gg 100\text{ m}^2\text{ g}^{-1}$). This intensity dominance by peaks due to bulk sites can be overcome if (1) the nuclei being observed are located only (or largely) at the surface or (2) the method of generating the polarization to be observed discriminates strongly in favor of nuclei at the surface. The former situation often obtains for protons in a typical silica, because most of the protons in such systems exist at the surface as covalently attached $-\text{OH}$ groups (vide infra), as physisorbed H_2O , or as covalently attached structures that result from derivatization processes.

Perhaps the most obvious strategy for preferentially or selectively polarizing surface nuclei in the presence of an overwhelmingly larger number of nuclei in analogous structural sites in the interior would be to use a relaxation reagent that can, at least briefly, interact with the surface and thereby relax the surface nuclei. Although surprisingly little effort seems to have been expended in this direction, one must note the elegant ultra-low-temperature ($\sim 10\text{ mK}$) NMR studies of Waugh and co-workers,⁶ who have used the relaxation effects of ^3He impinging on a surface for the selective relaxation of nuclei at the surface. Other surface-selective (or preferential) relaxation mechanisms would seem possible via the dipolar mechanism of impinging species with large nuclear magnetic moments (say, ^1H or ^{19}F) or even the electron spin magnetic moments of paramagnetic relaxation agents. In the case of paramagnetic surface relaxants, the possibility of dynamic nuclear polarization (DNP)⁷ of surface nuclei from adsorbed paramagnetic species seems attractive, possibly with the Overhauser mechanism operating if the adsorption is rapidly reversible, or the solid state mechanism if the adsorption/desorption process is very slow. Possibilities would also appear to exist for surface-selective relaxation mechanisms based on quadrupolar relaxation of a nuclide with $I > \frac{1}{2}$ (e.g. ^2H or ^{17}O) due to rapid, reversible adsorption/desorption causing a modulation of the local electric field gradient. Recent progress in the surface transfer of ^{129}Xe polarization that has been dramatically enhanced via electron $\rightarrow$ nuclear polarization transfer (e.g. from optically pumped rubidium) is promising for not only providing a surface-selective NMR strategy, but also for providing huge enhancements in the effective sensitivity of NMR detection at surfaces.⁸

2.2 Cross Polarization

To date, the most popular and generally successful surface-selective polarization strategies have been based on $^1\text{H} \rightarrow \text{X}$ cross polarization (CP),⁹ where X is a nucleus present at the surface (and presumably also with the bulk).^{10,11} These strategies are often based on the assumption that essentially all

Figure 1 Cross polarization as a surface-selective strategy, showing only protons near the (hatched) surface region, as covalently attached hydroxyls, physisorbed water, or physisorbed acids (B–H) of some other type. (Taken from Maciel and Ellis⁴)

(or, at least, most) of the protons in the system are present at the surface and on the fact that cross polarization depends upon a static component of the ^1H –X dipolar interaction, which has an inverse cube dependence on the ^1H –X internuclear distance (in many cases the cross polarization rate appears to have an essentially r^{-6} dependence). Cross polarization was developed during the early 1970s by Pines, Gibby, and Waugh.⁹ Its early impact was primarily the dramatic increase in ^{13}C signal-to-noise ratio in NMR experiments on organic solids, which rendered such experiments especially attractive when carried out with magic angle spinning (MAS), as demonstrated first by Schaefer and Stejskal.¹² From the point of view of surface applications, at least as important as the effective increase in sensitivity is the above-mentioned dependence of the cross-polarization rate on internuclear distances. Figure 1 displays the essence of a surface-selective CP strategy, in which only those X nuclei that are close enough to the surface (within, say, 5–6 Å, as represented by the ‘cross-hatched’ area) can be cross polarized by surface protons. The more remote X nuclei in the ‘interior’ or ‘bulk’ of the material are not cross polarized efficiently. Hence, the efficiency, or dynamics, of cross polarization can be used to discriminate in favor of the surface nuclei.

3 $^1\text{H} \rightarrow ^{29}\text{Si}$ CP IN SILICAS

3.1 Silica Gels and Derivatized Silica Gels

In 1980, Sindorf and Maciel^{10,11} published the first high-resolution example of the use of $^1\text{H} \rightarrow \text{X}$ cross polarization for surface-selective X detection in a demonstration of $^1\text{H} \rightarrow ^{29}\text{Si}$ CP in silica gel. Since that time $^1\text{H} \rightarrow ^{29}\text{Si}$ CP has remained the most popular application of this strategy, although there has been significant success with applications to other types of systems. Figure 2 shows typical ^{29}Si spectra of silica gel and related samples obtained by CP MAS (cross polarization and magic angle spinning) and DP MAS (direct polarization, based on ^{29}Si spin–lattice relaxation, not CP). The DP MAS spectrum [Figure 2(a)] of an undried silica gel is dominated by the peak due to $(\text{SiO})_4\text{Si}(\text{Q}_4)$ sites, which represent the bulk (nonsurface regions) of silica particles. The ^{29}Si CP MAS spectrum of an undried silica gel [Figure 2(b)] selects primarily surface sites and shows the following three peaks: a peak at –89 ppm (relative to liquid TMS) due to

Figure 2 ^{29}Si MAS spectra of silica gel samples. (a) DP MAS spectrum of an undried sample. (b) CP MAS spectrum of the same sample as in (a). (c) CP MAS spectrum of a sample dehydrated under vacuum at 209 °C. (d) Sample derivatized with $(\text{CH}_3)_3\text{SiCl}$. (Taken from Maciel⁵)

$(\text{SiO})_2\text{Si}(\text{OH})_2$ (geminal, Q_2) sites; a peak at –99 ppm arising from $(\text{SiO})_3\text{SiOH}$ (single silanol, Q_3) sites; and a peak at –109 ppm from the Q_4 (siloxane) sites near the surface. These peak assignments can be made on the basis of the usual kinds of empirical chemical shift correlations with structure from liquid sample data on silicic acid solutions. However, the dynamics of the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP process can also be used to make these assignments.

Figure 3 shows the results of a variable contact time CP experiment, in which the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP contact period (t_{cp}) is varied in order to elucidate the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP (relaxation) time constant (T_{Hsi}) for each ^{29}Si peak. The early (small t_{cp}) part of such curves is typically dominated by the rate of CP transfer, as characterized by the rate constant T_{Hsi}^{-1} , and the latter part of such curves is usually determined by the rate constant of the rotating frame spin–lattice relaxation of the protons responsible for polarization transfer to the observed silicons, as characterized by the time constant, $T_{1\rho}^{\text{H}}$ (assuming $T_{1\rho}^{\text{H}}/T_{\text{Hsi}}$). These curves can be analyzed mathematically in terms of equation (1),¹³

$$M(t_{\text{cp}})/M^* = \frac{1}{1 - T_{\text{Hsi}}/T_{1\rho}^{\text{H}}} (e^{-t_{\text{cp}}/T_{1\rho}^{\text{H}}} - e^{-t_{\text{cp}}/T_{\text{Hsi}}}) \quad (2)$$

Figure 3 Variable contact time ^{29}Si CP MAS plots for silica. (Taken from Maciel and Sindorf¹⁰)

where $M(t_{\text{cp}})$ is the ^{29}Si magnetization generated by ^1H – ^{29}Si CP as a result of a CP contact period t_{cp} , and M^* is the ‘ideal’ maximum ^{29}Si magnetization that would be generated if $T_{1\rho}^{\text{H}}$ and T_{HSi}^{-1} were both infinite. This analysis shows that T_{HSi}^{-1} for the -89 ppm peak is roughly twice that of the -99 ppm peak, which in turn is an order of magnitude larger than the T_{HSi}^{-1} value for the -109 ppm peak. In terms of the number and distances of nearby protons, the ^{29}Si chemical shift assignments given above in terms of Q_2 , Q_3 , and Q_4 sites are entirely consistent with these T_{HSi} determinations.

3.2 Dehydration of Silica

The ^{29}Si CP MAS spectra collected in Figure 2 also represent two important classes of chemical transformations of silica surfaces that were studied by ^{29}Si CP MAS spectra by Sindorf and Maciel.^{10,11,14–18} Figure 2(c) shows a spectrum obtained on a silica gel sample that has been dehydrated under vacuum at 209°C . One can see in this spectrum the subtle redistribution of peak intensity and the dramatic line broadening relative to the spectrum observed on an ‘air hydrated’ silica gel sample. These changes, especially the line broadening, are presumably due to a redistribution of hydrogen bonding patterns, and perhaps bond angles and bond lengths (and strains) introduced with the removal of the (predominantly physically) adsorbed water of the ‘hydrated’ and essentially ‘annealed’ silica surface represented in Figure 2(b). Such experiments carried out over a wide range of dehydration temperatures, and corresponding rehydration experiments, have revealed valuable information on the effects of dehydration and rehydration on the silica gel surface.

3.3 Silylation of Silica

The ^{29}Si CP MAS spectrum shown in Figure 2(d) represents a sample prepared by the silylation of a silica gel by $(\text{CH}_3)_3\text{SiCl}$. This silylation reaction is a member of an important class of derivatizations of the silica surface, represented by the following chemical equation:

where X represents a labile leaving group (e.g. Cl or OCH_2CH_3) and Si represents a silanol site on the reactant silica surface or a corresponding derivatized silica site in the reacted sample. Such reactions are important, or potentially important, technologically—for the preparation of stationary phases for chromatographic separations, as a means of immobilizing reactive chemical centers (e.g. catalytic sites), in coupling agents for composite materials, and for a wide range of other applications in which it is desired to anchor or ‘immobilize’ a chemically important moiety. Peak d in the spectrum of Figure 2(d), at ca. 10 ppm , is assigned to the trimethylsilyl group covalently attached to the silica surface. Clearly the silylation process has brought about a change of intensities of peaks a, b, and c in Figure 2(b), corresponding to the $(\text{SiO})_2\text{Si}(\text{OH})_2$ or Q_2 sites, the $(\text{SiO})_3\text{SiOH}$ or Q_3 sites, and $(\text{SiO})_4\text{Si}$ or Q_4 sites, at the underivatized surface. At the relatively low level of structural detail represented by the Q_2 , Q_3 , Q_4 notation, the silylation process transforms Q_2 sites into Q_3 sites, and Q_3 sites into Q_4 sites, and these changes are seen by comparing the spectra in Figure 2(b) and (d). By examining such intensity changes systematically, it has been possible to elucidate important reactivity patterns in these systems.^{10,11,14–18} Indeed, ^{29}Si CP MAS NMR, along with supporting data from ^{13}C CP MAS experiments, can serve as an analytical technique for monitoring chemical reactivity

Figure 4 ^{29}Si (right) and ^{13}C (left) CP MAS spectra of silica gel derivatized with $(\text{CH}_3)_2\text{Si}(\text{OCH}_2\text{CH}_3)_2$. (a) Product of reaction with predried silica at 138°C . (b) Product of reaction with predried silica at 240°C . (c) Product of reaction with undried silica at 115°C . (d) Sample (c) heated in air at 150°C . (Taken from Sindorf and Maciel¹⁷)

Figure 5 ^{29}Si CP MAS spectra of APTS-modified silica gels. Each column of spectra corresponds to the drying temperature of silica gel (°C; RT = room temperature) under vacuum prior to reaction in dry toluene, or aqueous reaction conditions (AQ). Postreaction treatment (curing) temperature shown on the left. Structural assignments given at the bottom. (Taken from Caravajal et al.¹⁹)

patterns, e.g. the relative reactivities of the various types of silanols on a silica surface.

The complex chemistry that can occur on a silica surface after silylation by a reagent with more than one leaving group (X), e.g. $\text{RR}'\text{SiX}_2$ or RSiX_3 , is also amenable to study by CP MAS NMR.¹⁷ In the ^{29}Si CP MAS spectra shown in Figure 4 one sees that the product formed initially from the reaction of silica with $(\text{CH}_3)_2\text{Si}(\text{OCH}_2\text{CH}_3)_2$ depends on the reaction conditions and predrying of the silica, and can be converted by the moisture in air [Figure 4(c), (d)] to products in which $\text{Si-OCH}_2\text{CH}_3$ moieties are replaced by Si-OH and ultimately Si-OSi- moieties. In this case, ^{13}C CP MAS spectra are also useful, because they detect the presence and amount of residual $\text{Si-OCH}_2\text{CH}_3$ moieties.

The ^{29}Si CP MAS spectra shown in Figure 5 represent an even more complex derivatized silica system, a series of samples prepared by the silylation of silica with 3-aminopropyltriethoxysilane (APTS) under a variety of conditions (pretreatment temperature = 200 °C for 200 series, or 110 °C for 110 series, 25 °C for RT series, or with silylation carried out in an aqueous slurry, AQ series).¹⁹ APTS-derivatization of the silica surface is of interest for such diverse applications as a variety of composite materials (in which APTS serves as a coupling agent between a silica-like component and, usually, an organic polymer) and for metal complexation agents. One sees from the spectra of Figure 5 that increasing the amount of water in the silylation process or increasing the postsilylation 'curing' temperature brings about changes in attached silane populations from species with

one Si-OSi attachment (-49 ppm) to species with two such attachments (-58 ppm) to three such attachments (-66 ppm). Although ^{13}C spectra are primarily useful for monitoring the residual $\text{Si-OCH}_2\text{CH}_3$ moieties in this system, a careful analysis of the ^{13}C CP MAS spectra of samples corresponding to those represented in Figure 5 reveals that the ^{13}C chemical shift of the central carbon of the pendant $-(\text{CH}_2)_3$ -group originating from APTS is sensitive to protonation or hydrogen bonding of the amino group. ^1H CRAMP spectra (vide infra) and ^{15}N CP MAS spectra are also useful for studying this important issue.

3.4 Fumed Silica

Other types of silicas (and derivatized silicas), besides those based on silica gels, have also been studied by ^{29}Si CP MAS (and DP MAS) experiments, e.g. by Brinker and co-workers^{20,21} and by Legrand and co-workers.^{22,23} Figure 6 shows a comparison of ^{29}Si CP MAS spectra of a fumed silica (a Cab-O-Sil, formed by the vapor-phase combustion of SiCl_4) and a silica gel equilibrated to about the same H_2O vapor pressure.²⁴ The same peaks are present, but they are broader in the case of the fumed silica, and the percentage of surface silica sites that are single silanols is seen to be smaller for the fumed silica than for silica gel. The greater linewidth presumably relates to the greater dispersion of local surface geometries (and chemical shifts) in the Cab-O-Sil structure, which is formed at a higher temperature, and possibly to

Figure 6 ^{29}Si CP MAS spectra of (a) Cab-O-Sil fumed silica and (b) silica gel. Top: experimental spectra. Bottom: individual Q_2 , Q_3 , and Q_4 peaks by deconvolution. Middle: computer sum of the contributions shown at the bottom. (Taken from Liu and Maciel²⁴)

Figure 7 ^{29}Si CP MAS spectra of polysiloxane polymer prepared from $\text{Si}(\text{OEt})_4$ and $(\text{CH}_3\text{O})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{Cl}$ with (a) $\text{Bu}_2\text{Sn}(\text{OAc})_2$ or (b) 0.1 M HCl as catalyst. (Taken from Elnahhal et al.²⁶)

the potential effects of so-called ‘interparticle sites’ at the junctures of the primary particles that contribute to the overall topography of a fumed silica.²³ Detailed studies of ^{29}Si CP MAS spin dynamics of fumed silicas, especially when viewed in relationship to analogous silica gel results, appear promising for identifying the main similarities and differences between these two types of silica surfaces.²⁴

3.5 Polysiloxane Systems

There has been a great deal of interest recently in a class of polysiloxane polymers prepared by the hydrolysis

and gelation of mixtures of reagents of the types, $\text{Si}(\text{OR}')_4$ and $\text{RSi}(\text{OR}'')_3$, where R' and R'' are typically methyl or ethyl and R is a ‘pendant’ group that contains some desired chemical moiety, e.g. a specific ligand.²⁵ By varying the nature of R and the ratios of the two types of starting reagents, a wide range of polysiloxane materials, with a broad variety of potentially useful properties, can be prepared. These polysiloxane materials bear a substantial similarity to derivatized (silylated) silicas, with a silica-like three-dimensional network to which the pendant (R) groups are attached. Hence, the NMR techniques that are useful for characterizing derivatized silicas are also useful for these polysiloxane systems.

Figure 7 shows ^{29}Si CP MAS spectra of polysiloxane systems with $-\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl}$ as the pendant group, prepared by the reaction of $\text{Si}(\text{OEt})_4$ with $(\text{MeO})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{Cl}$, using two different catalysts.²⁶ One notes substantially different intensity ratios for the Q_2 , Q_3 , and Q_4 peaks in the two spectra [and possibly a Q_1 peak at about -82 ppm in Figure 7(b)], and for the peaks due to the pendant groups (at about 60 and 65 ppm), as well as a dramatic difference in intensities between the 60 and 65 ppm peaks relative to the Q_2 , Q_3 , Q_4 peaks, for the products from the two catalyst systems employed.

4 $^1\text{H} \rightarrow ^{17}\text{O}$ CROSS POLARIZATION

In addition to cross polarization to ^{29}Si in silica, or to ^{13}C (or ^{15}N , ^{31}P , etc.) in derivatized silicas, cross polarization to ^{17}O in isotopically-enriched silicas has also been illuminating. Oldfield and co-workers have during the past several years made significant progress in the application of solid state ^{17}O NMR techniques for the characterization of inorganic materials. Walter, Turner, and Oldfield²⁷ have demonstrated that $^1\text{H} \rightarrow ^{17}\text{O}$ CP experiments are not only feasible, but they are also very informative from the point of view of editing ^{17}O spectra, by discriminating against ^{17}O signals from oxygen sites with no directly bonded hydrogen. Figure 8 shows $^1\text{H} \rightarrow ^{17}\text{O}$ CP spectra of amorphous silica and a model SiOH system. From a comparison of the spectra obtained from static samples and by MAS, with and without CP, it was possible to assign the ^{17}O signal due to SiOH groups at the surface.

5 PROTON NMR APPROACHES

5.1 Dipole–Dipole Broadening

High-resolution ^1H NMR spectroscopy has proved to be highly useful in studying the surfaces of silicas and a variety of other solids. In order to obtain high-resolution ^1H NMR spectra of solids (including their surfaces), it is necessary to average not only the chemical shift anisotropy (easily done by MAS), but also ^1H – ^1H dipolar interactions.^{28,29} The latter can be very large (tens of kHz). Magnetic dipole–dipole interactions manifest an inverse cube dependence on internuclear distance. Therefore such interactions, and the ^1H – ^1H spin–spin flip-flops that they can generate, are especially strong if the protons are situated in close proximity to each other, e.g. in a typical organic solid, but also perhaps in hydrogen-bonded clusters of hydroxy groups on a surface. Hence, a priori one can feel confident that moderate-speed MAS experiments (say, less

Figure 8 Static and MAS ^{17}O spectra of amorphous SiO_2 and polycrystalline $(\text{C}_6\text{H}_5)_3\text{SiOH}$ obtained at 67.8 MHz. (a) ^1H -decoupled static spectrum of SiO_2 without CP: 108 scans. (b) ^1H -decoupled MAS spectrum: 100 scans, 7.6 kHz spinning speed (*indicates spinning sidebands). (c) $^1\text{H} \rightarrow ^{17}\text{O}$ static spectrum of SiO_2 , 200 scans, 0.1 ms contact time. (d) $^1\text{H} \rightarrow ^{17}\text{O}$ MAS spectrum of SiO_2 , 200 scans, 0.1 ms contact time. (e) ^1H -decoupled static spectrum of $(\text{C}_6\text{H}_5)_3\text{SiOH}$ without CP: 500 scans. (f) ^1H -decoupled MAS spectrum of $(\text{C}_6\text{H}_5)_3\text{SiOH}$: 800 scans, 4.0 kHz spinning speed. All spectra were obtained using a 2 s recycle time. (Taken from Walter et al.²⁷)

Figure 9 The multiple pulse line-narrowing strategy for averaging homonuclear dipolar interactions. Each rectangle [between (a) and (b)] represents one multiple pulse cycle (e.g. four pulses for WAHUA, eight for MREV-8 or 24 for BR-24). There is one data acquisition point for each cycle (e.g. between each rectangle). (Taken from Maciel⁵)

than 20 kHz) are adequate for studying silica surfaces only for substantially dehydrated samples. For nondehydrated or nondeuterated samples, in which the *local* surface density of protons can be substantial, multiple pulse techniques may be required for eliminating the line-broadening effects of ^1H - ^1H dipolar interactions. Alternatively, a useful strategy employed by Vega and co-workers is to ensure that the ^1H concentration is small by exchanging protons at the surface with deuterons.³⁰

5.2 Multiple Pulse Line Narrowing: CRAMPS

In 1968, Waugh and co-workers³¹ introduced a *multiple pulse* approach for averaging strong homonuclear dipolar interactions. The strategy of this kind of approach is that, over the *entire* period of each individual multiple pulse cycle (four 90° pulses in the original work), the average Hamiltonian that governs the evolution of the spins over the entire cycle does not include the homonuclear dipolar interaction. A nonvanishing chemical shift effect, albeit scaled down, is present in the average Hamiltonian. Hence, if one acquires one data point stroboscopically between each adjacent pair of multiple pulse cycles in a long string of such cycles, the resulting time-dependent signal (analogous to a free induction decay) is

Figure 10 ^1H NMR spectra of citric acid. (a) Static sample, single pulse, (b),(c),(d) MAS-only with indicated MAS speed. (e) and (f) CRAMPS. (Taken from Dec et al.³⁵)

modulated by chemical shift effects, but not by homonuclear dipolar effects. The strategy is outlined in Figure 9 in which each rectangle represents a multiple pulse cycle and each asterisk represents a data acquisition point. The bandwidth of the experiment depends on $1/t_c$, the inverse of the multiple pulse cycle time.

The original homonuclear line-narrowing pulse sequence (WAHUA)³¹ was a four pulse sequence; later elaborations involve more pulses in the total cycle and offer compensation for pulse imperfections and/or higher order averaging of the homonuclear dipolar interaction.^{32,33} In general, this class of experiments requires short ($<1.5\ \mu\text{s}$), powerful 90° pulses with precisely defined phases and until recently has been technically one of the most difficult experiments in the solid state NMR laboratory. Currently, the most popular multiple pulse sequences are the eight pulse MREV-8 sequence³² and the 24 pulse BR-24 sequence.³³

For powdered or amorphous samples, in order to avoid line broadening due to chemical shift anisotropy, magic angle spinning is employed (which also averages various heteronuclear dipolar couplings). Gerstein and co-workers³⁴ were the first to combine a multiple pulse homonuclear

Figure 11 ^1H NMR spectra of untreated silica gel. (a) Static sample, single pulse. (b),(c),(d) MAS-only with indicated MAS speed. (e) CRAMPS. (f) CRAMPS on an expanded scale. (Taken from Dec et al.³⁵)

line-narrowing technique with magic angle spinning, and introduced the acronym CRAMPS for Combined Rotation And Multiple-Pulse Spectroscopy.^{28,29}

5.3 ^1H CRAMPS Studies of Silicas

Figures 10 and 11 show the difference in ^1H line-narrowing capabilities between CRAMPS and MAS-only (no multiple pulse sequence) with a modestly high MAS speed (10–11 kHz).³⁵ For powdered crystalline citric acid (Figure 10), one sees six distinctly resolved ^1H CRAMPS peaks, but essentially no resolution in the 10.7 kHz MAS-only ^1H spectrum. This difference reflects the high proton concentration (~ 29 atom %) and molecular rigidity of crystalline citric acid. For the more proton-dilute (~ 2.5 atom %) silica gel system (Figure 11), the ^1H NMR experiment yields a modestly narrowed ^1H spectrum even on a static sample, and 4.7 kHz MAS yields a spectrum that is superficially similar to that obtained by CRAMPS. However, close inspection reveals important details that differentiate the ^1H spectra obtained by these two techniques [Figure 11(d) and (e)]. All of the remaining ^1H spectra discussed in this article were obtained by the CRAMPS technique.

One should note that the CRAMPS technique is not necessarily a panacea for ^1H NMR studies on surfaces, or for any other type of sample. Dynamics associated with motion and/or chemical reactions with a time constant that is comparable to the cycle time (t_c) of the multiple pulse sequence interferes with the multiple pulse averaging of

^1H – ^1H dipolar interactions.^{29,36} Of course, an analogous problem can also arise with magic angle spinning, for which the critical period is ν_{MAS}^{-1} , where ν_{MAS} is the MAS frequency.³⁷ To quench this kind of dynamic interference with the line-narrowing efficiency of any cyclic technique, like MAS and/or a multiple pulse sequence, one can try to alter the dynamics, e.g. by changing (usually lowering) the sample temperature.

As an example of the application of the ^1H CRAMPS technique to the study of silica surfaces,³⁸ Figure 12 shows the ^1H CRAMPS spectra obtained on untreated [Figure 12(a), (a'), (a'')] and dried [Figure 12(b), (c), (d)] silica gel samples. Comparison of spectra (a) and (b) show that the relatively sharp peak at about 3 ppm in the spectrum of an untreated silica is removed by moderate dehydration; this peak is therefore identified as physisorbed water. The broad nonsymmetrical peak that is largely to the left of the sharp 1.9 ppm peak is unaffected by sample evacuation at 200 °C, but removed by evacuation at 500 °C; this behavior suggests that this peak can be identified tentatively with clustered (or hydrogen bonded) silanols, which are close enough together that suitable dehydration pathways are available. The sharp peak at 1.9 ppm remains after evacuation at 500 °C; this behavior implies that the silanol groups represented by this peak are sufficiently far from each other to make dehydration difficult, so it is assigned to isolated (non-hydrogen-bonded) silanols. These assignments are consistent with 35 years of literature results on liquid solution samples, which show that hydrogen bonding typically reduces proton shielding, and with the reasonable point of view that a wide range of hydrogen-bonding structures exist on a silica surface (chemical shift dispersion: broad peak). These assignments are also consistent with the results of proton dipolar-dephasing experiments, as shown in Figure 13.

5.4 CRAMPS-Based Time Domain Studies of Silicas

Figure 13(a) shows a ^1H CRAMPS version³⁸ of the popular 'dipolar-dephasing' experiment used routinely in ^{13}C CP MAS NMR. In this ^1H CRAMPS version, a 'dephasing period' 2τ is inserted between the initial $\pi/2$ pulse that generates transverse magnetization and the multiple pulse line-narrowing pulse train that detects the transverse magnetization. During the dephasing period, those proton magnetic moments that experience strong dipolar interactions undergo a corresponding degree of dephasing, and the resulting detected signal will be accordingly attenuated. Figure 13(b) and (c) show the results of applying the dipolar-dephasing CRAMPS experiment to untreated silica gel [Figure 13(b)] and to a silica gel sample evacuated at 200 °C [Figure 13(c)]; in both cases one sees that the broad (3.0 ppm) peak is attenuated by a dephasing period (2τ) of 160 μs , whereas the sharp (1.7 ppm) peak is largely unattenuated. From the relationship between hydrogen bonding and proximity (between atoms that participate in a hydrogen bond) and the r^{-3} dependence of dipolar interactions, this dipolar-dephasing behavior provides strong support for identifying the 1.7 ppm peak as arising from isolated (non-hydrogen-bonded) silanols and the broad 3.0 ppm peak as clustered (hydrogen bonded) silanols. This is the same conclusion regarding proximity (and hydrogen bonding) that one would reach from the dehydration behavior shown in Figure 12. It would be difficult to rationalize the elimination

Figure 12 187-MHz ^1H CRAMPS spectra of Fisher S-679 silica gel. (a) untreated; (b) evacuated at 25 °C; (c) evacuated at 200 °C; (d) evacuated at 500 °C; (a'') deconvolution of spectrum (a); (a') computer simulation based on (a''). (Taken from Bronnimann et al.³⁸)

Figure 13 ^1H CRAMPS dipolar-dephasing experiment. (a) Pulse sequence. (b) results for untreated silica gel (showing τ values). (c) Results for sample evacuated at 200°C (showing τ values). (Taken from Bronnimann et al.³⁸)

of water via the ‘dehydration’ of silanols that are *isolated* from each other. Since the physisorbed water peak (3.5 ppm) is only slightly attenuated by the $160\ \mu\text{s}$ dephasing period [Figure 13(b)], one can conclude that water protons experience only weak resultant dipolar interactions, the result of efficient motional averaging.

Other CRAMPS-based ^1H time domain approaches have also been useful in studying silica surfaces. Figure 14 summarizes a CRAMPS-detected T_1^{H} determination on silica gel samples, based on an alternating, two-sequence scheme of the Freeman–Hill type.³⁹ One sees that for each of the two silica samples, untreated (b) and dried (c), all components of proton magnetization relax essentially homogeneously, which suggests that proton spin diffusion among the different spin isochromats is much more efficient than spin–lattice relaxation, which is characterized overall by T_1^{H} values of 0.7–4 s. Furthermore, the marked increase in T_1^{H} that results from sample drying indicates that the physisorbed water in the sample of Figure 14(b) provides an important relaxation source, and is presumably in a rapid state of motion at room temperature.³⁶ Having the ability to establish, via dipolar dephasing, different spin polarizations for hydrogen bonded

Figure 14 ^1H CRAMPS T_1 determination. (a) Pulse sequence, showing individual sequences employed in alternate scans (lower case subtracted from upper case in computer memory). (b) Results for untreated silica gel (showing τ values). (c) Results for sample evacuated at 25°C . (Taken from Bronnimann et al.³⁸)

and isolated silanols, one can explore spin exchange between these two spin sets by an experiment of the type shown in Figure 15(a).³⁸ One sees for the untreated silica [Figure 15(b)] that in a mixing time of a few ms after eliminating ^1H magnetization due to hydrogen-bonded silanols there is a substantial transfer of magnetization (spin exchange) from the isolated silanol reservoir to the hydrogen-bonded silanol protons. In any attempt to interpret or model the structure of the silica surface, the rate of this spin exchange places constraints on the spatial proximities of these two proton spin sets in terms of the dipole–dipole interactions that can be responsible for ^1H – ^1H flip-flops, and/or chemical (H^+) exchange.

A variety of CRAMPS-based ^1H NMR experiments of the types represented in Figures 12, 13, 14, and 15 have been carried out on silica samples in which there have been systematic variations of physisorbed water content or dehydration, and often temperature. Figure 16 shows ^1H CRAMPS dipolar-dephasing results obtained at room temperature on three different silica gels.³⁶ The behavior shown is consistent with the ideas described above. Figure 17 shows ^1H CRAMPS spectra of a hydrated (exposed to air) silica gel over a temperature range from 138 K to 298 K.³⁶ An effective freezing point depression of about 45 K can be noted from these kinds of measurements; this result is consistent with previous reports based on other types of experiments.⁴¹

Figure 16 ^1H CRAMPS dipolar-dephasing spectra of three different silica gels. (a) Untreated. (b) Modestly dehydrated (2.6% weight loss). (c) Drastically dehydrated (at 500°C)

5.5 Derivatized Silicas

Figures 18 and 19 show ^1H CRAMPS spectra of silica surfaces that have been derivatized with $(\text{CH}_3)_3\text{SiCl}$ and

Figure 17 ^1H CRAMPS spectrum of an untreated silica gel as a function of temperature, as shown

$(\text{CH}_3\text{CH}_2\text{O})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ (APTS), respectively. These spectra show that this technique can provide a rich level of structural detail on derivatized silica samples. The difference between the spectra of unprotonated and protonated APTS-derivatized samples (Figure 19) is the absence and presence, respectively, of a clearly distinct peak corresponding to the amino group of APTS.²⁹ This difference reflects, at least in part, the interference of ^{14}N quadrupole effects of the $-\text{NH}_2$ group with MAS averaging of $^1\text{H}-^{14}\text{N}$ dipolar interactions. Calculations on $=\text{N}-\text{H}$ groups show that, because of the small internuclear $\text{N}-\text{H}$ distances for directly bonded pairs, very high NMR fields ($>1000\text{ MHz}$) would be required to reduce this broadening to an acceptable level by the 'brute force' approach of simply going to a higher field.⁴²

6 CORRELATING ^1H -BASED AND ^{29}Si -BASED INFORMATION

6.1 Complementary Results

While one can distinguish between hydrogen bonded and isolated silanols by ^1H CRAMPS experiments and between single silanols and geminal silanols by ^{29}Si CP MAS experiments, it is important to correlate these two types of information. Ideally, one would base such a correlation on two-dimensional (2D) $^1\text{H}-^{29}\text{Si}$ heteronuclear chemical shift

Figure 18 ^1H CRAMPS spectrum of trimethylsilyl-derivatized silica gel

Figure 19 ^1H CRAMPS spectra of APTS-modified silica gel. Lower, untreated. Upper, treated with HCl. (Taken from Maciel et al.²⁹)

correlation (HETCOR) experiments of the general type that are employed routinely for $^1\text{H}-^{13}\text{C}$ correlation in liquids and more recently in solids.^{43,44} Indeed, Vega has reported such experiments based on $^1\text{H} \rightarrow ^{29}\text{Si}$ CP for the polarization transfer step.⁴⁵ However, as is seen below, rotating frame ^1H spin diffusion among the protons in a typical silica gel during the spin lock state in a $^1\text{H} \rightarrow ^{29}\text{Si}$ CP experiment can substantially scramble what one would hope are discrete $\text{H} \leftrightarrow ^{29}\text{Si}$ CP correlations in the time frame ($>200\ \mu\text{s}$) required for relatively efficient CP transfer. Furthermore, the multiple

(Taken from Chuang et al.⁴⁷)

pulse approaches used in ^1H - ^{13}C HETCOR experiments on solids are not very efficient in these ^1H - ^{29}Si systems, although recently reported successes in ^1H - ^{31}P 2D HETCOR experiments on P-O-H systems⁴⁶ indicate that ^1H - ^{29}Si HETCOR in silica may be attractive. In any case, as an alternative to the 2D HETCOR approach, a variety of ^{29}Si -detected ^1H - ^{29}Si CP experiments have been carried out, in which the behavior of protons is monitored by ^{29}Si , establishing the correlation.⁴⁷

6.2 ^{29}Si Detection of Proton Spin Behavior

The simplest such experiment is a ^{29}Si CP MAS experiment in which ^{29}Si detection is carried out *without* proton decoupling. MAS should still average the ^1H - ^{29}Si dipolar interaction during detection, yielding a corresponding sideband pattern to the extent that this interaction behaves inhomogeneously, i.e. to the extent that the ^1H - ^{29}Si dipolar interaction is not altered (by chemical reaction, motion, or ^1H - ^1H flip-flops) during a MAS rotor period.⁴⁷ Figure 20 shows a comparison of spectra obtained with and without ^1H decoupling; it is

clear that the geminal silanol peak suffers most dramatically from the absence of high-power ^1H decoupling, implying that ^1H spin exchange is most efficient in the protons of geminal silanols.

Another ^{29}Si CP MAS experiment useful for correlating ^1H and ^{29}Si spin behaviors is the ^1H - ^{29}Si analog of the common ^1H - ^{13}C dipolar-dephasing experiment. In this technique, rotational and Hahn echo formation occur for a dephasing period (2τ) corresponding to two MAS rotor periods ($2\tau_{\text{rot}}$) for the isotropic ^{29}Si chemical shift, the ^{29}Si chemical shift anisotropy, and the ^1H - ^{29}Si dipolar interaction (to the extent that it behaves inhomogeneously).⁴⁷ Figure 21 shows results of the ^1H - ^{29}Si dipolar-dephasing ^{29}Si CP MAS experiment with the dephasing period ranging over more than $4\tau_{\text{rot}}$. Focusing on the points at $2\tau = 0$, $2\tau_{\text{rot}}$ and $4\tau_{\text{rot}}$, one sees very little dephasing decay for the Q_4 (siloxane) signal, and more efficient decay for the Q_2 (geminal silanol) signal than for the Q_3 (single silanol) signal. This again suggests more efficient ^1H - ^1H spin diffusion among the $=\text{Si}(\text{OH})_2$ protons than among $\geq\text{SiOH}$ protons.

A very direct correlation of ^1H CRAMPS dipolar-dephasing behavior with ^{29}Si CP MAS signals is obtained in the experiment shown in Figure 22, in which there is a 2τ ^1H - ^1H

Figure 21 Plots of deconvoluted peak integrals of the 39.75-MHz ^{29}Si CP MAS NMR spectra of Fisher S-679 silica gel versus ^1H - ^{29}Si dipolar-dephasing time up to four rotor periods. CP contact time, 5 ms; magic angle spinning speed, 2.0 kHz. Vertical dashed lines show odd numbers of rotor periods and vertical solid lines show even numbers of rotor periods. (a) -89 ppm peak (geminal silanols); (b) -99 ppm peak (single silanols); (c) -109 ppm peak (siloxane silicons). (Taken from Chuang et al.⁴⁷)

dipolar-dephasing period *before* CP transfer to ^{29}Si .⁴⁷ Taking account of the rotational echo behavior of ^1H magnetization, for $2\tau = 2nt_{\text{rot}}$ essentially all relevant proton interactions refocus except the ^1H - ^1H dipolar interaction. Hence, the magnetization of those protons involved in the strongest (shortest, least mobile) hydrogen bonds is most effectively dephased during $2\tau = 2nt_{\text{rot}}$ and unavailable for CP transfer to ^{29}Si . Figure 23 shows the results obtained on a silica gel sample. For a CP contact time (t_{cp}) that is small enough ($100\ \mu\text{s}$) to avoid the rotating frame spin diffusion that scrambles the desired ^1H - ^{29}Si correlation (vide supra), the geminal silanol peak at -89 ppm is the one that suffers most from ^1H - ^1H dipolar dephasing for a $2t_{\text{rot}}$ period. The effect of rotating frame proton spin diffusion is also clear from the spectra in Figure 23: if a long CP contact period (e.g. 1–5 ms) is employed, essentially the same relative peak intensities are

Figure 22 ^{29}Si CP MAS NMR experiment with ^1H - ^1H dipolar-dephasing prior to $^1\text{H} \rightarrow ^{29}\text{Si}$ cross polarization. (Taken from Chuang et al.⁴⁷)

Figure 23 ^{29}Si CP MAS NMR spectra of Fisher S-679 silica gel obtained with $2\ \mu\text{s}$ (top spectrum of each set) and two rotor periods (1.04 ms; bottom spectrum of each set) of ^1H - ^1H dipolar-dephasing prior to four different ^1H - ^{29}Si CP contact times. Magic angle spinning speed, 1.9 kHz. (a) $t_{\text{cp}} = 100\ \mu\text{s}$ (top spectrum, 7376 accumulations; bottom spectrum, 82 504 accumulations); (b) $t_{\text{cp}} = 300\ \mu\text{s}$ (top spectrum, 2400 accumulations; bottom spectrum, 46 200 accumulations); (c) $t_{\text{cp}} = 1\ \text{ms}$ (top spectrum, 432 accumulations; bottom spectrum, 21 232 accumulations); (d) $t_{\text{cp}} = 5\ \text{ms}$ (top spectrum, 600 accumulations; bottom spectrum, 8320 accumulations). (Taken from Chuang et al.⁴⁷)

obtained whether or not the $2t_{\text{rot}}$ ^1H - ^1H dipolar-dephasing period is included in the experimental sequence.

One overriding theme emerges from all the results embodied in Figures 20–23: the protons that are primarily responsible for cross polarization to geminal silanol silicons are much more extensively involved in hydrogen bonding than are the protons primarily responsible for cross polarization to single silanol silicons. This theme is consistent with structural models of the

Figure 24 Side views of specific silicon planes (dashed line representing an edge of such a plane) of β -cristobalite. Drawing approximately to scale: (a) 111 face; (b) 100 face; (c) vicinal sites from dehydration of the 100 face. (Taken from Chuang et al.⁴⁷)

silica surface (or, at least fragments of it) that correspond to specific faces of a β -cristobalite crystal.^{47,48}

Figure 24 shows views looking 'into' the 111 and 100 faces, which contain single silanols (Q_3) and geminal silanols (Q_2), respectively. From the O–O distances between hydroxyl oxygens of these surfaces, we see that one should expect hydrogen bonding between adjacent geminal silanols, but not between adjacent single silanols; this is in agreement with the NMR results summarized above. Of course, the silica surface is not a homogeneous one, and may be describable as a composite of these two types of surfaces, with suitable interfaces. The geometrical relationship between silanols that are adjacent *across* these interfaces is important in the overall hydrogen-bonding patterns at silica surfaces. Furthermore, the presence of water on the surface dramatically changes the pattern of hydrogen bonding, including the establishment of hydrogen-bonding networks among the single silanols.

7 SUBSURFACE SILANOLS

An implicit assumption on which the use of ^{29}Si CP MAS as a kind of surface-selective technique is based is the following: essentially all (or at least most) of the protons of a sample like SiO_2 are at the surface. This assumption has been tested in a variety of ways, including ^{29}Si NMR. One NMR avenue for testing this assumption is to examine the ^1H and/or ^{29}Si

Figure 25 ^{29}Si CP MAS spectra of silica gels stirred in H_2O or D_2O at 25°C or 100°C , as indicated

NMR spectra of samples that have been subjected to repeated exchanges with D_2O . Figure 25 shows the ^{29}Si CP MAS spectra of silica gel samples that have been treated in this way.⁴⁰ From such studies, it has been determined that for a typical silica gel, 91–97% of the silanols are exchangeable with D_2O , the exact percentage depending on the time and temperature of the exchange. The geminal silanol signal is completely depleted by D_2O exchange, and Figure 26 shows that this signal is immediately restored to its equilibrium intensity shortly after a D_2O -exchanged silica is exposed to the moisture in air. Hence, none of the inaccessible or subsurface silanols are of the Q_2 type.

Extensive studies of spin dynamics in D_2O -exchanged samples have revealed a substantial amount of detail about the local environment and motional dynamics of 'internal' silanols in silica gel.⁴⁰ The T_{HSi} values indicate that the hydroxy groups of 'internal' silanols rotate freely about the Si–O axis in a manner similar to the rotation of non-hydrogen-bonded silanols on a dehydrated silica surface. Analogous studies have also been carried out on a fumed silica Cab-O-Sil.²⁴ While the D_2O -exchange behavior and various features of ^1H and ^{29}Si spin dynamics in Cab-O-Sil are qualitatively similar to what is discussed above for silica gel, some significant and possibly important differences are observed,²⁴ perhaps because of interparticle (particle bridging) silanols that have been suggested by some authors for fumed silicas.

8 SUMMARY AND CONCLUSIONS

MAS NMR approaches based on ^1H and ^{29}Si are enormously useful in the characterization of silica surfaces, including derivatized silica surfaces. The CRAMPS technique, and especially dipolar-dephasing elaborations, provide a powerful way to distinguish between hydrogen bonding and isolated silanols. Silicon-29 CP MAS spectra clearly distinguish between Q_2 , Q_3 , and Q_4 sites at the surface. Via $^1\text{H} \rightarrow ^{29}\text{Si}$ cross polarization, the ^{29}Si CP MAS technique provides avenues for projecting ^1H spin behavior onto a ^{29}Si NMR spectrum. D_2O -exchange approaches allow the use of ^1H and ^{29}Si NMR behavior to examine subsurface or trapped silanols.

1 INTRODUCTION

Catalysis is playing an increasingly important role in a variety of industries and has become a very significant contributor to the world economy. For example, the total value of fuels and chemicals derived through catalysis in the USA exceeds 20% of the US gross national product. Today, most of the applications of industrial significance use heterogeneous catalysis, the term being restricted to catalytic phenomena involving a solid catalyst and reactants in a gas or liquid phase. The first industrial heterogeneous catalytic reaction was introduced over 100 years ago and used platinum to oxidize SO_2 to SO_3 ; other important processes soon followed. Metal catalysts are of great significance in heterogeneous catalysis, particularly in processes involving hydrogen (e.g. hydrogenation, hydrogenolysis, and catalytic reforming) and in oxidation reactions. In most applications metals are used in the form of small particles (typically 1–10 nm) highly dispersed on thermally stable materials with large surface area, such as metal oxides, zeolites, and silica.

As the use of catalysis has continued to grow, so has the need for a basic understanding of catalytic processes. A realistic description of catalytic reactions requires both detailed information on catalytic surfaces and a fundamental knowledge of the nature and dynamics of the elementary phenomena involved. This knowledge, along with past experience and intuition, should make it possible to develop catalysts that are more active, selective, stable, and less expensive. Despite the enormous growth of surface science in the last two decades, the understanding of how catalysts work continues to be insufficient. Although most researchers still use traditional methods (e.g. volumetric, gravimetric, and reactor studies, calorimetry, and microscopy), spectroscopic studies are essential for gaining further insight into elementary processes on surfaces. Most of the spectroscopic methods used to investigate single crystal metal surfaces require ultrahigh vacuum, and cannot be applied to working catalysts; however, X-ray spectroscopies, infrared spectroscopy, and, lately, NMR have become the tools of particular value. Several review articles have been already published which summarize the early^{1,2} and recent^{3,4} NMR results.

The use of NMR begins with characterization of metal surfaces and then correlation of this information with catalytic performance. Such studies can be performed directly by using NMR of metals or by observing probe molecules adsorbed on the metal surface. NMR can be also used in its traditional role as a tool to study the structure of reactants and products and to perform quantitative investigations under conditions typical of catalytic reactions. In addition, NMR has the ability to probe the dynamics of all processes that are essential for catalysis, including diffusion, adsorption, and reaction. This article describes and discusses some of these significant applications.

2 SAMPLES

The metals most commonly used for catalysis involve elements from Group VIII of the Periodic Table (e.g. Co, Ni, Ru, Rh, Pd, and Pt), and Cu, used in pure or mixed (e.g. bimetallic) form. The supports include alumina (Al_2O_3), silica (SiO_2), titania (TiO_2), silica–alumina, and aluminosilicates (zeolites), usually synthesized in a highly porous form with characteristic surface area ranging from few to about $1000 \text{ m}^2 \text{ g}^{-1}$. The metals are deposited on supports by impregnation or ion exchange, which is usually followed by drying, calcination, and reduction that result in the formation of metal particles. Loadings of 1–2 wt % or more are common in industrial catalysts but can be as high as 20 wt % in catalysts used for the laboratory studies. Only a small fraction of the support is covered with metal, and the average interparticle distances are usually several times larger than the particle size. Depending on the metal and the support used, and the preparation conditions, dispersions range between about 1.0 and < 0.05 which corresponds to particle sizes of about 1–50 nm and 10^{19} – 10^{20} of metal surface sites per gram of catalyst. Particles bigger than 2 nm consist largely of low index plane facets, and their adsorption sites are similar to those on single crystals. However, in highly dispersed metals, the number of lower coordinated sites increases significantly. For example, a perfect cuboctahedral particle composed of 586 atoms has 272 atoms on the surface (and the corresponding dispersion of $272/586 = 0.345$), 44% of which are less than nine-fold coordinated, e.g. occupying edge and corner sites. In a larger cuboctahedral particle composed of 37 766 atoms, the corresponding values are 4332, 0.13 and 27%, respectively. In real catalysts a distribution of particle sizes can exist with a variety of possible shapes and irregularities that further increase the number of low coordinated sites.

Prior to adsorption, the metal surfaces are cleaned and activated. The detailed descriptions of these procedures and the adsorption conditions can be found in the literature and are thus not given here. Only note that in the studies of catalytic processes, the results are strongly susceptible to small changes in the way that adsorbents and adsorbates are prepared and brought into contact as well as in the conditions of the measurements.

3 NMR OF METALS

The most ‘NMR-friendly’ metal nuclei that are of interest in catalysis include ^{63}Cu ($I = \frac{3}{2}$, natural abundance 69%, and

relative sensitivity versus ^1H of 9.3×10^{-2} , ^{109}Ag ($I = \frac{1}{2}$, 48%, about 10^{-4}), and ^{195}Pt ($I = \frac{1}{2}$, 34%, about 10^{-2}). The NMR properties of these nuclei in bulk metals are dominated by the Knight shift interaction between nuclear spins and the conduction electrons. A detailed review of the theory and experimental data can be found elsewhere⁵ (see also **Knight Shift**), and only a brief description of this phenomenon is given below. The hyperfine interaction between the electron and nuclear spin I can be written as:

$$\hat{\mathcal{H}}_{en} = -\gamma_n \hbar \hat{I} \cdot \mathbf{B}_{\text{eff}} \quad (1)$$

where γ_n is the nuclear gyromagnetic ratio and $\mathbf{B}_{\text{eff}}$ is the effective magnetic field induced by an electron at the nuclear site. The position of the NMR line is determined by the time average value of $\hat{\mathcal{H}}_{en}$ due to all electrons in the metal. In para- and diamagnetic substances, this value is nonzero only in the presence of an external magnetic field $\mathbf{B}_0$, and the NMR frequency is usually proportional to that field:

$$\omega_0 = \gamma_n (1 + K) B_0 \quad (2)$$

where $(\gamma_n B_0)/2\pi$ describes the frequency of a reference, and K is the resonance shift which in metals includes the Knight shift and the generally smaller chemical shift. Three terms can contribute to $\hat{\mathcal{H}}_{en}$: the Fermi contact interaction, the dipolar interaction, and the interaction with electronic orbital moment. The dipolar term results in line broadening but does not change the resonance frequency. The orbital term is responsible for the chemical shift and is usually much smaller than the Knight shift. The Knight shift results from the contact interaction, described by the Hamiltonian:

$$\hat{\mathcal{H}}_c = \frac{8\pi}{3} \gamma_e \gamma_n \hbar^2 \hat{I} \cdot \hat{S} \delta(\mathbf{r}) \quad (3)$$

where γ_e is the electronic gyromagnetic ratio and $\mathbf{r}$ is the vector that has its origin at the nuclear site and describes the position of the electron spin $\mathbf{S}$. The main contribution to the Knight shift is from the s electrons because their wave function does not vanish at the nuclear site.

An extensive ^{195}Pt NMR study of small particles of platinum supported on alumina has been performed by Slichter and co-workers.^{6–8} The samples consisted of about 10 wt % platinum with dispersions between 4% and 58%, as determined by hydrogen chemisorption. Due to large inhomogeneous broadening of the NMR lines (3–5 MHz at the frequency of 74 MHz), only a small fraction of the nuclei could be excited in a single experiment, and the spin echo mapping technique was used to measure the NMR lineshapes (see Figure 1). In this technique, the intensities produced by an add–subtract spin echo pulse sequence at different values of the static magnetic field $\mathbf{B}_0$ and at a fixed frequency were plotted, point by point, to produce the complete NMR spectrum.⁶

The spectra shown in Figure 1 exhibit a full distribution of Knight shifts in the samples with platinum particles of different dispersions and subjected to various types of treatment. The Knight shift in bulk platinum results from a direct contact interaction with the 6s electrons [high-frequency (downfield) shift] and a core polarization via the 5d electrons (low-frequency shift). The net effect of these two contributions results in a low-frequency shift of about 4% of the ^{195}Pt resonance in the bulk platinum relative to the nonmetallic compounds. In Figure 1 the bulk ^{195}Pt nuclei located in the interior of platinum particles are represented by a sharp

Figure 1 ^{195}Pt NMR lineshapes for several alumina-supported platinum catalysts: (a)–(d) Untreated catalysts (exposed to air) with dispersions of 0.04, 0.15, 0.46, and 0.58, respectively; (e) same as (c) but adsorbed molecules cleaned from the surface by alternate flow of O_2 and H_2 , each followed by evacuation at 600 K; (f) same as (e) but again exposed to hydrogen and air for several weeks. All spectra were measured at 77 K using a spin echo mapping technique. (Reproduced by permission of The American Physical Society from H. E. Rhodes, P.-K. Wang, H. T. Stokes, C. P. Slichter, and J. H. Sinfelt, *Phys. Rev. B*, 1982, **26**, 3559)

feature in the low-frequency portion of the spectrum at $B_0/v_0 \approx 0.114 \text{ T MHz}^{-1}$. Note that this feature is only observed in samples with less dispersed, large particles. The contributions from the contact interaction of the 6s electrons and 5d core polarization progressively cancel for nuclei located in a less bulk-like environment, i.e. closer to the particle surface. Almost complete cancellation occurs at the surfaces of particles when they are covered with adsorbed molecules. In this case, the surface platinum atoms are tied up in chemical bonds and lose their metallic character.⁷ In the spectra shown in Figure 1, the surface platinum is represented by the high-frequency, narrow peak at $B_0/v_0 = 0.1089 \text{ T MHz}^{-1}$. This assignment was verified by measuring the areas of this peak relative to the total intensity of the spectrum, which correlated well with the platinum dispersions obtained from hydrogen chemisorption. Furthermore, the use of SEDOR allows resolution of the NMR spectrum of the surface layer of platinum particles coated with ^{13}C enriched CO .⁸ In this experiment, the magnetization of ^{13}C spins was flipped concurrently with the ^{195}Pt π pulse, which modified the ^{195}Pt spin echo amplitude for the spins located at the particle surface. By subtracting appropriately scaled signals measured with and without ^{13}C π pulses, the surface ^{195}Pt spins could be singled out in the NMR spectra (see Figure 2). The final width of the SEDOR line results from distribution of isotropic Knight shifts at different platinum sites, anisotropy of chemical shifts, and anisotropic hyperfine coupling.⁸

Significant changes in the ^{195}Pt lineshape were observed upon removal of the adsorbed species from the platinum surface [Figure 1(e)]. The narrow high-frequency peak disappeared and the intensity of the ‘metallic’ portion of the

Figure 2 ^{195}Pt NMR lineshape at 77 K obtained with spin echo mapping and SEDOR for platinum particles (dispersion 0.26) adsorbed with CO. (Reproduced by permission of The American Physical Society from D. Makowka, C. P. Slichter, and J. H. Sinfelt, *Phys. Rev. B*, 1985, **31**, 5663)

spectrum increased, suggesting that for the platinum atoms on a clean surface the 5d–6s Knight shift cancellation is not complete (although still greater than in the bulk metal). The ^{195}Pt NMR lineshape in Figure 1(c) was restored upon exposure of the catalyst to air for several weeks [Figure 1(f)]. The spectra shown in Figures 1 and 2 were reproduced by lineshape calculations based on a phenomenological model of the spatial variation of the Knight shift in the platinum particles.⁸ Similar ^{195}Pt NMR studies were performed on titania-supported platinum particles.⁹

The NMR of ^{109}Ag was applied to study silver particles supported on Al_2O_3 and SiO_2 by Mastikhin.¹⁰ In the bulk metal the ^{109}Ag nuclei are located in a highly symmetrical environment of cubic, face-centered, metal crystals and exhibit a narrow [about 200 Hz full width at half maximum (FWHM)] resonance with a Knight shift of 5000 ppm (to high frequency relative to water solution of AgNO_3). The ^{109}Ag NMR of supported catalysts showed that the resonance from the bulk metal was only observed for samples containing particles larger than 40 nm. The ‘nonmetallic’ silver particles (<40 nm) could not be detected, presumably because of longer spin–lattice relaxation times, greater linewidth, or both. A similar effect was reported in a ^{63}Cu NMR study on a series of silica-supported copper catalysts by Gerstein and coworkers.¹¹ In this case, the electric field gradient asymmetries near the copper surface were too large to allow detection of the surface nuclei, and the reduced catalysts showed only one resonance characteristic of the $\text{Cu}(0)$ bulk copper. However, the surface atoms could be observed after chloriding the surface of copper with HCl gas. The intensity of the ^{63}Cu NMR peak assigned to CuCl showed good agreement with the amount of surface copper determined by a reaction with nitrous oxide.¹¹

4 PROTON NMR

Hydrogen is the simplest and most important of all adsorbates and plays a dual role in catalysis; it is not only a reactant or product in many catalytic reactions but also can be a powerful probe for investigating the surface of the

catalyst. In addition, it is the most common of all NMR active nuclides, and with about 100% natural abundance and a large magnetic moment is relatively easy to detect on surfaces. The earliest ^1H NMR work involved hydrogen adsorbed on Al_2O_3 - and SiO_2 -supported platinum,¹² TiO_2 -supported rhodium,^{13–15} and all platinum metals (Ru, Rh, Pd, Os, Ir, and Pt) supported on SiO_2 .¹⁶ The samples used in these studies were sealed in glass tubes and measured at room temperature under single pulse excitation. Later work included more complicated catalytic systems, e.g. bimetallic catalysts¹⁷ and promoted metals,¹⁸ and involved more advanced NMR methods: selective excitation, two-dimensional NMR, and in situ NMR at variable pressures and temperatures.¹⁹ In general, application of MAS and decoupling techniques did not lead to increased resolution in ^1H NMR on supported metals because of the heterogeneity of samples and the high intrinsic mobility of hydrogen.

A set of ^1H NMR spectra for supported rhodium, ruthenium, and copper is shown in Figure 3. Each spectrum shows a peak at about 0 ppm (from TMS), which represents diamagnetic hydrogen on the support, mainly in OH groups, and hydrogen that spilled over from the metal. Other resonance lines in the spectra represent hydrogen interacting with the metal and are usually observed outside of the chemical shift range for ^1H (0–15 ppm). The observed resonance frequency and lineshape depend on the type of metal, conditions under which the metal surface was prepared, particle size, temperature, and hydrogen pressure.^{13,15–20} For hydrogen adsorbed on the Group VIII metals, low-frequency shifts of ^1H NMR lines are observed, ranging from less than –20 ppm for osmium to above –140 ppm for rhodium,¹⁶ whereas hydrogen on copper has a high-frequency shift of about 90 ppm. Although

Figure 3 ^1H NMR spectra of hydrogen adsorbed at 4000 Pa on supported catalysts: (a) Rh/TiO_2 ; (b) Ru/SiO_2 ; (c) Cu/SiO_2

Figure 4 Model of a catalyst in the presence of hydrogen

in most studies only one resonance line is observed arising from hydrogen on metals, the presence of several types of adsorbed hydrogen species was inferred from the analysis of NMR data. The large shifts in the spectra shown in Figure 3 are associated with the Knight shift—the polarization of the adsorbed hydrogen species occurs because of the bonding overlap between the hydrogen 1s orbitals and the conduction s electrons or the d electrons of the underlying metal. In general, Knight shifts decrease with increasing coverages due to pairing of the electron spins in the metal by chemisorbed hydrogen. At high coverages the observed shift can be affected by exchange processes with other types of adsorbed species, H_2 gas, or both.

A scheme representing the supported catalyst surface in the presence of hydrogen is shown in Figure 4. Probing catalyst surfaces with 1H NMR presents a variety of opportunities: (i) studies of the chemical composition and structure of the metal particles; (ii) studies of the interaction between the metal and the support; (iii) determination of concentrations of various hydrogen species on the metal and the support (intrinsic and spill over); and (iv) measurements of the dynamics on surfaces, including transport phenomena, molecular or atomic mobility, exchange rates between various species, adsorption and desorption rates, and activation energies.

4.1 Studies of Metal Surfaces by 1H NMR: the SMSI Effect

Determining the surface chemical composition, dispersion, and electronic properties and how these factors affect catalyst performance is crucial for understanding the mechanisms of catalytic reactions. The questions of primary importance are: What is the dispersion of the metal? Which atoms are present on the surface? How do these atoms interact with the underlying atomic layers?

The standard method for determining metal dispersion uses volumetric measurement of hydrogen uptake and is based on the assumed surface hydrogen-to-metal stoichiometry $H/M = 1$. This assumption is supported by investigations of single crystals using X-ray diffraction and transmission electron microscopy (TEM). However, the irreversible spill-over of hydrogen from the metal to the support may result

Figure 5 In situ 1H NMR spectra of hydrogen at 400 K on an Ru/SiO₂ catalyst (dispersion 0.30, Ru loading 8 wt %) at various H_2 pressures. (Reproduced by permission of The American Physical Society from F. Engelke, S. Bhatia, T. S. King, and M. Pruski, *Phys. Rev. B.*, 1994, **49**, 2730)

in overestimating the H/M ratio when using the volumetric technique. Quantitative measurements of hydrogen uptake by NMR are obtained by comparing the intensity of the adsorbed hydrogen with that of a reference standard. Several studies on the supported Ru, Rh, Pt, Ru–Cu, Ru–Ag, Ru–Au, and other systems clearly showed the advantage of an NMR method for estimating dispersions because of NMR's ability to distinguish and measure the adsorption states on the support in addition to the metal.^{15, 17, 18, 21}

Figure 5 shows a series of 1H NMR spectra of the Ru/SiO₂ catalyst adsorbed with varying amounts of hydrogen at room temperature. The spectra were acquired by using an in situ NMR probe attached to a volumetric adsorption apparatus. This technique allowed investigation of catalytic systems in steady-state equilibria at variable temperatures and pressures that could be easily and precisely controlled during the experiments.^{19–21} Under low-pressure conditions (133×10^{-5} – 133×10^{-1} Pa) a resonance α_1 at about -60 ppm was observed, which represented dissociatively adsorbed (chemisorbed) hydrogen on ruthenium that could not be removed from the surface by short evacuation at room temperature. The integrated intensity of this peak measured after 10 min evacuation is used as an estimate of metal dispersion. At elevated pressures the weakly adsorbed hydrogen species are observed. First, an increase of the peak at about -60 ppm occurs as the pressure rises from 133×10^{-1} to 133×10^2 Pa (hydrogen α_M), whereas another hydrogen species (β) is detected at about -45 ppm upon further elevation of pressure to above 133×10^2 Pa.^{19, 20} The nature and dynamics of hydrogen at elevated pressures are described later.

In addition, NMR can be used to investigate the chemical composition of metallic particles. The particles composed of more than one metal (e.g. bimetallic) often exhibit surface composition much different from what the catalyst synthesis would suggest. Also, small particles of the catalyst precursor may react with the support, resulting in partial or complete encapsulation of the metal surface and thus lowering their catalytic activity. Characterization of SiO₂-supported Ru–Cu bimetallic catalysts by Wu et al.¹⁷ is an excellent example of such a study. In this work the ¹H NMR spectra were measured for a series of Ru–Cu/SiO₂ catalysts prepared with various copper loadings (Figure 6). The bimetallic clusters were formed on silica by coimpregnation with copper atoms which blanketed the ruthenium in a manner similar to chemisorption. A resonance at about –60 ppm observed at 0 atom % copper shifted to high frequency with the increasing coverage of ruthenium by copper. For a copper loading >40 atom % a resonance characteristic of hydrogen on bulk copper appeared at 90 ppm, indicating the formation of larger copper islands on ruthenium or buildup of separate copper particles.

Two different hydrogen spill-over processes were found in this catalyst system: (i) the hydrogen-on-metal NMR

intensities indicated a spill-over from ruthenium to copper, and (ii) a spill-over from the metal onto the support was measured by comparing the NMR spectra with the hydrogen uptake from volumetric studies. More importantly, the surface compositions of Ru–Cu particles could be obtained from the observed NMR shifts.¹⁷ If one assumes a fast exchange between hydrogen on ruthenium and copper, the lineshift δ_{obs} , from Figure 6, can be expressed as the weighted average:

$$\delta_{\text{obs}} = X_{\text{Ru}}\delta_{\text{Ru}} + X_{\text{Cu}}\delta_{\text{Cu}} \quad (4)$$

where δ_{Ru} and δ_{Cu} are lineshifts for hydrogen on ruthenium and copper deposited on ruthenium, and X_{Ru} and X_{Cu} are surface fractions of ruthenium and copper, respectively. Since $X_{\text{Ru}} + X_{\text{Cu}} = 1$, the surface fraction of ruthenium can easily be obtained from the NMR data. Figure 7 shows the surface fraction of ruthenium plotted against copper content and compared with a theoretical curve for monolayer coverage. Clearly, copper preferentially segregates to the ruthenium surface and in so doing covers the ruthenium in a monolayer fashion before forming three-dimensional copper islands, pure copper particles, or both. The ¹H NMR experiments performed for the Ru–Ag and Ru–Au systems showed the formation of three-dimensional particles at much lower silver and gold contents (Figure 7).²²

The so-called strong metal–support interaction (SMSI) effect, which leads to suppression of H₂ and CO adsorption after a high-temperature reduction of the metal–support system, is often observed in Group VIII metals supported on TiO₂. Possible explanations of this effect include: (a) migration of a reduced form of titania (TiO_x) onto the metal surface, resulting in a physical blockage of the metal sites; and (b) an electronic interaction, either via an electron transfer from the reduced, hydrogen-rich support to the metal, or from the metal to the nonreduced, hydrogen-free support. NMR proved instrumental in studying the SMSI effect. For the Rh/TiO₂ catalyst, the NMR studies indicated that, in addition to the formation of strongly bonded hydrogen on rhodium, a

Gerstein, and T. S. King, *J. Catal.*, 1990, **123**, 43)

weakly adsorbed species exists. For this species a mechanism was proposed that implied dissociation at the metal–support interface followed by proton stabilization on the support, most likely at the Rh–TiO₂ borderline.¹⁴ This hydrogen affects the surface electronic states of the metal, which is manifested by the decreasing Knight shift of the hydrogen atoms irreversibly bonded to rhodium. As a result of a fast chemical exchange between the two species, only one low-frequency resonance was observed with a shift that could be roughly approximated by the weighted average of strongly and weakly adsorbed species. Also proposed was a metal-to-support electron transfer mechanism that generates Ti³⁺ ions in the vicinity of metal particles, which may be followed by stabilization of H[−] species at the surface of the oxide. This electron injection from the metal to the support was proposed to induce the SMSI effect as it reduced the density of states at the Fermi level of rhodium and thereby reduced its capacity to adsorb hydrogen. The hydride-type species on the support were shown to be reversibly generated, and the SMSI condition could be removed by evacuation at elevated temperatures. For that reason the SMSI effect was not explained by the encapsulation of rhodium with TiO_x species migrating from the support, although partial coverage of the rhodium surface or other morphological changes of the metal particles were not ruled out.¹⁵

Other studies proved quite unambiguously that at least partial encapsulation of metal particles by TiO_x occurs in Ru/TiO₂ catalysts upon high-temperature reduction or during catalyst preparation. Recently, a combination of in situ ¹H NMR, TEM, and H₂ chemisorption was used to determine the metal particle size, the fraction of metal surface available for H₂ chemisorption, and the H₂ adsorption capacity of the catalyst as a function of the reduction temperature.²¹ The true particle size of dispersed ruthenium was determined from TEM micrographs, and the fraction of exposed ruthenium atoms was determined by in situ ¹H NMR. By combining these two techniques a quantitative estimate of the extent of ruthenium particle encapsulation was measured as the reduction temperature varied between 470 and 770 K. Since no change in particle size with a reduction temperature was observed by TEM, the decrease in the ratio of hydrogen irreversibly adsorbed on ruthenium to the total amount of ruthenium (H_{i,Ru}/Ru_{total} in Figure 8) was attributed to the progressive coverage of ruthenium particles by TiO_x. The evidence of an amorphous overlayer of TiO_x on ruthenium was also shown in the TEM micrographs. In addition, the extent of hydrogen spillover onto the TiO₂ (H_{i,TiO₂} in Figure 8) was estimated by NMR. This study showed that while ¹H NMR provided an accurate measure of the exposed metal surface available for chemisorption, H₂ volumetric chemisorption could not be reliably used to determine dispersion of a Ru/TiO₂ catalyst, even after reduction at temperatures as low as 473 K, because irreversible hydrogen spill-over from the metal caused this method to overestimate the result. This conclusion implies that turnover frequencies based on volumetric hydrogen uptake cannot be accurate. ¹H NMR and TEM showed no encapsulation of ruthenium by silica in a Ru/SiO₂ catalyst.²¹ These results are consistent with similar phenomena found on TiO₂[−] and SiO₂[−] supported platinum catalysts by using ¹⁹⁵Pt NMR.⁹

4.2 Dynamics of Hydrogen on Surfaces

The NMR studies of dynamics of hydrogen adsorbed on catalysts (adsorption, desorption, diffusion, and exchange) are of great interest since these processes cannot be characterized by most surface spectroscopic techniques. The NMR methods used for these studies depend on the timescale of the dynamic process:

1. The measurements of the longitudinal (spin–lattice) relaxation time T_1 and the longitudinal relaxation time in the rotating frame $T_{1\rho}$ can be used to study relatively fast motions. The T_1 and $T_{1\rho}$ relaxation processes are generally associated with dipolar fields fluctuating at the frequencies $\omega_0 = \gamma B_0$ and $\omega_1 = \gamma B_1$ (where B_1 is the rf magnetic field), respectively. Such fields are generated by motions of other magnetically active nuclei or unpaired electron spins, with correlation times $\tau_c \approx (\omega_0)^{-1}$ for T_1 (nanosecond and microsecond range) and $\tau_c \approx (\omega_1)^{-1}$ for $T_{1\rho}$ (microsecond and millisecond range). The analysis of relaxation has been widely applied to study mobilities of molecules adsorbed on zeolites. On supported metals, however, other sources of relaxation (e.g. Knight shift interaction, collisions with molecules in the gas phase) may supplement the motional effect, rendering this technique less efficient.
2. The analysis of NMR lineshapes has been routinely used to detect slower motions associated with the static spin interactions in solids, characterized by $\tau_c \approx (\Delta\omega)^{-1}$, where $\Delta\omega$ is the NMR linewidth ($10^{-6} \text{ s} < \tau_c < 10^{-2} \text{ s}$). By applying spin labeling techniques (e.g. selective excitation by DANTE or by using a ‘soft pulse’), two-dimensional NMR techniques, or field gradient methods, slower motions with $(\Delta\omega)^{-1} < \tau_c < T_1$ can be studied.
3. The isotope labeling method proved to be a powerful tool for probing the dynamic processes with $\tau_c > T_1$.

A recent review by Duncan⁴ and several articles in this Encyclopedia (see *Adsorbed Species: Spectroscopy and Dynamics* and *Chemical Exchange on Solid Metal Surfaces*)

discuss these methods in more detail. Demonstrated below is a study of several dynamic processes for hydrogen adsorbed on Ru/SiO₂. As outlined earlier, there are various types of hydrogen species present in this system: strongly and weakly adsorbed hydrogen on ruthenium, hydrogen that spilled over to the support, hydrogen in surface OH groups, and H₂ gas (Figure 4). These species undergo different types of motion, including exchange.

The line broadening of irreversibly adsorbed hydrogen α_1 on ruthenium [about 10 kHz FWHM, see Figure 5(a)] is mainly inhomogeneous, due to distribution of Knight shifts and particle sizes and to heteronuclear ¹H–Ru dipolar coupling.¹⁹ The two-dimensional NMR spectra, based on the pulse sequence $[(\pi/2)_x-t_1(\text{evolution})-(\pi/2)_{-x}-\text{mixing}-(\pi/2)-t_2(\text{acquisition})]$, revealed that the homogeneous linewidth of α_1 is only about 2 kHz. This linewidth can be explained by assuming hydrogen located at the average distance of 0.5 nm, which is consistent with the estimated metal coverage H_{Ru}/Ru of about 0.5. However, a remarkable change occurs in the two-dimensional spectra as the H_{Ru}/Ru ratio increases to about 1.5 at a hydrogen pressure of 10.7 kPa.¹⁹ A linewidth of about 3 kHz is now observed, which is approximately the same as in the one-dimensional NMR spectrum shown in Figure 5(b). Calculating the corresponding second moment due to ¹H–¹H dipolar interactions yields about 20 kHz for rigid spins, and about 10 kHz assuming two-dimensional diffusion. Clearly, at elevated pressures hydrogen α_M undergoes three-dimensional motion sufficient to average out the dipolar interaction, i.e. the correlation time for this process $\tau_c \ll (2\pi \times 20 \text{ kHz})^{-1} \approx 10 \mu\text{s}$. This type of motion can be understood by assuming hydrogen whirling around the metal particles without desorbing from the surface. However, exchange between different particles via a quick desorption–interparticle diffusion–adsorption process was recently found to be a more likely scenario. Similarly, the β -hydrogen was shown to be highly mobile.¹⁹

One of the exchange processes in this system occurs between adsorbed hydrogen and the H₂ gas, with both species contributing to the β peak in Figure 5.¹⁹ The H₂ gas resonates at about 0 ppm and on pure silica could be easily distinguished from the OH resonance by using a T_1 inversion–recovery experiment. The absence of this peak for the catalyst indicated the fast exchange between nonadsorbed and weakly adsorbed hydrogen with time $\tau_{ex} \ll (2\pi \Delta\nu)^{-1} \approx 10 \mu\text{s}$, where $\Delta\nu \approx 14 \text{ kHz}$ is an approximated difference of resonance frequencies for the exchanging species. On the basis of this model, the pressure dependence of the β resonance shift (which moved to high frequency with increasing pressure) was explained, and the relative mole fractions of the exchanging species were calculated by using a formula analogous to equation (4).¹⁹

The presence of separate NMR lines for hydrogen α and β in the single pulse spectra shown in Figure 5 implies that these two species are not exchanging on the timescale of this experiment, meaning that the time constant for exchange is $\tau_{ex} > (2\pi \Delta\nu_{\alpha\beta})^{-1} \approx 50 \mu\text{s}$. However, the slow exchange process between α and β could be detected in a two-dimensional exchange NMR spectrum, that revealed cross peaks after a mixing time of 2 ms. The time constant for this process (about 700 μs at 400 K) was measured by monitoring the evolution of magnetization of both resonance lines after one of them was selectively inverted with the DANTE-type pulse sequence

(a similar experiment can be performed by using a two-dimensional exchange sequence with a fixed evolution time and various mixing periods).¹⁹

Finally, a very slow exchange process between hydrogen adsorbed on ruthenium and silanol protons was monitored by hydrogen–deuterium exchange.¹⁸ The time constant τ_{ex} of about 12 h was measured for this process at room temperature for the catalyst dosed with 666 Pa of deuterium at the onset of the experiment. For the deuterium-dosed sample that was subsequently evacuated, no exchange was observed, which suggested that the exchange between the reversibly adsorbed hydrogen and silanol protons occurred via the spilt-over hydrogen that acted as an intermediate in this process.

5 ADSORPTION AND REACTION OF SIMPLE MOLECULES ON SUPPORTED METALS

Studies of adsorption and transformation of hydrocarbons on catalyst surfaces are the most important and challenging problems in catalytic chemistry. The detailed description of the structure and dynamics of adsorbed species and the changes induced upon variation of temperature and coverage can provide insight into the mechanisms of surface reactions. The main reason NMR spectroscopy became a highly esteemed tool in these studies is its ability to observe the nuclei of ¹³C. The possibility of identifying various species via the isotropic shifts or by analysis of nuclear dipolar couplings is of primary importance. In addition, ¹³C NMR has the ability to probe molecular dynamics by using many of the concepts and methods similar to those described previously for protons. Because of the low natural abundance of ¹³C (1.1%) and its low relative sensitivity, most of these studies are performed by using ¹³C-enriched molecules and require extensive data acquisition times.

5.1 Studies of CO on Metals

Carbon monoxide is one of the most studied adsorbates in surface science. It has received special attention as a model system and because of the technological importance of catalytic hydrogenation of CO. The chemisorption and reaction of CO on Group VIII metals was traditionally observed by using infrared (IR) spectroscopy; however, after the first report of the ¹³C spectra of CO on rhodium and ruthenium by Duncan et al.,²³ these studies have extended to solid state NMR.^{1–4}

Carbon monoxide occurs on supported metals in one of three basic structures—linear, bridging, or multicarbonyl—which (in the absence of the Knight shift) exhibit the isotropic chemical shifts of 185 (± 15), 220 (± 20), and 185 (± 15) ppm, respectively. In general, the linear and bridging structures are formed on metal sites on extended surfaces, with the ratio between the two depending on the metal, surface geometry, coverage, and temperature; multicarbonyls, on the other hand, are mainly formed with isolated atoms. The static ¹³C NMR spectra of adsorbed CO can be fitted by assuming typical CSA powder patterns for the three structures that are convoluted with appropriate broadening functions. Because of the low signal-to-noise ratio and the number of fitting parameters involved, additional information regarding particle

morphology and the amount of adsorbed CO is often needed to reduce the ambiguities. The dicarbonyl species may give rise to several lineshapes: (i) a full powder pattern characteristic of rigid species (which is indistinguishable from linear CO); (ii) a narrower (by a factor of 2) and reversed lineshape proposed for $\text{Rh}(\text{CO})_2$ species undergoing a 180° flipping motion about the C_2 axis that bisects the C–Rh–C angle (as shown by Molitor and Apple using a Carr–Purcell–Meiboom–Gill multiple pulse sequence²⁴); and (iii) a Lorentzian component that is motionally narrowed, e.g. via rotation about both the Si–O and O–Rh bonds. An example of a ^{13}C NMR spectrum for CO on highly dispersed Rh/SiO_2 is shown in Figure 9.²⁵ A four-component simulation was used to fit the data, as explained in the figure.

Although the static ^{13}C NMR spectra of CO bonded on metals are broadened due to CSA, clean CSA patterns are rarely observed because they are often overwhelmed by inhomogeneous broadening imposed by the distribution of adsorption sites, Knight shifts, and magnetic susceptibility. The susceptibility is of the order of $(4\pi/3)\chi$, where χ is the static magnetic susceptibility of the metal particle, and has an

Figure 9 ^{13}C NMR spectrum of CO adsorbed on Rh/SiO_2 with a four-component least-squares fit. The rigid component represents linear CO on rhodium particles and immobile $\text{Rh}(\text{CO})_2$ species; the Lorentzian and flipping components are interpreted as mobile and flipping $\text{Rh}(\text{CO})_2$; and bridging represents Rh_2CO . (Reproduced by permission of the American Chemical Society from A. M. Thayer and T. M. Duncan, *J. Phys. Chem.*, 1989, **93**, 6763)

effect comparable to ^{13}C CSA.² The exact calculation of line broadenings associated with the Knight shift and susceptibility is difficult, since both depend on the particle size (in general, they decrease with increasing dispersion) and adsorbate. These factors can reduce the resolution of the NMR spectra to the extent that only one broad Gaussian peak is observed. For example, a lineshape of ^{13}C measured by Slichter and coworkers on $\text{Pt}/\text{Al}_2\text{O}_3$ exhibits a >300 ppm broad Gaussian line shifted 200 ppm to high frequency from the CO gas.²⁶ The Knight shift was shown to arise from mixing of 5σ orbital of CO with the conduction electrons of the platinum particle (Knight shift). The T_1 relaxation of ^{13}C obeyed the Korringa relationship $T_1 \cdot \text{Temperature} = \text{Constant}$, and was independent of the magnetic field, which is consistent with the Knight interaction being operable in this system. Larger Knight shifts (resonance position at about 750 ppm) were found for CO on palladium but were negligibly small for CO on rhodium and ruthenium.²⁷

MAS was first employed in the studies of CO by Gay, who introduced a system for the stable spinning of samples sealed in glass vials at speeds exceeding 3 kHz.²⁸ The MAS spectrum of ^{13}C on Ru/SiO_2 revealed a 17 ppm wide peak located at 194 ppm and assigned to linear CO (Figure 10). The narrowing effect of MAS was significant in this case because the static spectrum was 400 ppm wide. Several other studies following this work achieved various degrees of success in terms of spectral resolution.^{4,27,29,30} For example, Duncan et al.²⁹ reported high-resolution ^{13}C NMR spectra of CO on Ru/SiO_2 and Rh/SiO_2 that showed isotropic peaks consistent with linearly bonded CO and multicarbonyl CO on isolated metal atoms, but failed to detect bridged CO, whose presence was inferred from the analysis of the static spectra. In contrast, substantial amounts of bridging CO were observed in a study of a Rh/SiO_2 catalyst by Gay.³⁰ However, MAS appeared rather ineffective in narrowing the CO resonances on supported metals with relatively large magnetic susceptibilities, such as platinum and palladium. For example, Zilm et al. measured static and MAS ^{13}C spectra of CO adsorbed on a series of Pt/SiO_2 , $\text{Pt}/\eta\text{-Al}_2\text{O}_3$, and $\text{Pd}/\gamma\text{-Al}_2\text{O}_3$ catalysts.²⁷ Both static and MAS spectra of ^{13}C on platinum exhibited a >400 ppm wide, slightly asymmetric peak with a first

Figure 10 Static (a) and MAS (b) spectra of ^{13}C on an Ru/SiO_2 catalyst. (Reproduced by permission of Academic Press from I. D. Gay, *J. Magn. Reson.*, 1984, **58**, 413)

moment M_1 of about 350 ppm from TMS. A motionally narrowed featureless peak found at 750 ppm on palladium also remained unaffected by MAS. The spin–spin couplings of any kind were insignificant relative to the broadening observed, and the inefficiency of MAS was not found to be the result of molecular motion. Clearly, large distributions of shift-like (linear in the magnetic field) interactions exist in these samples, resulting in different Knight shifts, chemical shifts, and magnetic susceptibilities experienced by ^{13}CO that depended on the adsorption site as well as the metal particle size and shape.²⁷ Even for systems in which it remains ineffective for line narrowing, however, MAS provides useful information about the variation of adsorption sites responsible for the inhomogeneous broadening and can also be used in the studies of molecular dynamics. (For more detail, see Section 5.2.)

The strong dependence of dipolar couplings between nuclei on the internuclear distance ($\hat{H} \propto r^{-3}$) is often used to study the geometrical arrangements of interacting spins. On metal surfaces, the NMR lineshapes obtained by using single pulse excitation cannot be used to study dipolar couplings since the characteristic spectral features of dipolar broadened spectra are obscured by CSA, the Knight shift, and magnetic susceptibility. However, these inhomogeneous interactions can be refocused by suitable spin echo techniques and will then yield the NMR decays modulated only by the weaker dipolar coupling. For example, Slichter and co-workers³¹ demonstrated that a simple spin echo sequence ($\pi/2-\tau-\pi-\tau$ -observe) when applied to a system consisting of homonuclear pairs of coupled spins (e.g. $^{13}\text{C}-^{13}\text{C}$), can produce oscillations (called ‘slow beats’) of the echo envelope versus τ . After the Fourier transformation, these oscillations give rise to a Pake doublet and provide an accurate measure of nearest-neighbor internuclear distances. The slow beat analysis was applied to study the distribution of chemisorbed CO molecules on supported platinum. By analyzing the echo envelopes for a series of platinum catalysts with various ^{13}CO coverages, the contribution to relaxation from dipolar interactions between ^{195}Pt and ^{13}C was separated from $^{13}\text{C}-^{13}\text{C}$ spin echo decays. When the measured decays were compared with theoretical predictions for various arrangements of CO on Pt(111) and Pt(100), the geometry of the CO layer was inferred and the formation of islands of CO on platinum particles was demonstrated at low coverages.

The heteronuclear dipolar couplings can be studied by using the previously described SEDOR technique. In the studies of CO, the $^{195}\text{Pt}-^{13}\text{C}$ SEDOR experiment was used to determine the Pt–C distance of CO bonded to platinum. Also, $^{13}\text{C}-^{17}\text{O}$ SEDOR allowed the determination of the C–O bond length of ^{13}C - and ^{17}O -enriched CO chemisorbed on palladium.³² In the ^{17}O NMR experiment, the signal was enhanced by cooling the sample to 4 K and by using the Carr–Purcell method to acquire several echoes within each time interval T_1 .

The CO motion on metals can be characterized by using the NMR methods similar to those described previously for hydrogen. An example of the relaxation analysis is the study of CO on platinum.²⁶ The results showed that a distribution of relaxation times T_1 existed at 77 K, whereas a single exponential decay was observed at 290 K. The averaging of relaxation at room temperature suggested the diffusion of CO over the platinum surface. This diffusion process could be studied in greater detail by monitoring the NMR linewidth

as a function of temperature.^{2,3} Using this technique gave an activation energy of $E = 29 \text{ kJ mol}^{-1}$ for the diffusion of CO on Pt. The ^{13}C resonance line narrowed from >400 ppm to about 50 ppm around room temperature, with the remaining broadening due to variation of isotropic shifts from particle to particle. Further motional narrowing was observed in this catalyst at about 560 K and was attributed to interparticle diffusion of CO with activation energy $E = 100 \text{ kJ mol}^{-1}$.^{2,3}

Slower motions of CO were studied by Duncan et al. on supported rhodium and ruthenium by using the spin population labeling technique.^{4,33} For catalysts that exhibit well-defined CSA powder patterns and exhibit motions that are slower than the reciprocal linewidth, a selective inversion of a narrow portion of these spectra (hole burning) can be performed. This inversion results in labeling the CO molecules with a C–O bond orientation in the external magnetic field depending on the position of the ‘hole’ in the spectrum (Figure 11). The motional process can be studied by monitoring the nonequilibrium magnetization created by the labeling pulse as a function of recovery time. In addition, the mathematical

Figure 11 ^{13}C NMR spectra of CO chemisorbed on an Ru/SiO_2 catalyst as a function of recovery time after hole burning at 300 ppm. (Reproduced by permission of the American Institute of Physics from T. M. Duncan, A. M. Thayer, and T. W. Root, *J. Phys. Chem.*, 1990, 92, 2663)

models which describe evolution of the hole profile for several models of CO dynamics (desorption, surface–gas exchange, and various types of surface diffusion) were developed. For CO adsorbed on ruthenium, the recovery of the hole resulted from surface diffusion on multifaceted particles, and its temperature dependence between 298 and 375 K indicated that the activation energy for this process was $E = 22.6 \text{ kJ mol}^{-1}$.³³

5.2 Studies of Simple Hydrocarbon Molecules and their Reactions

Understanding the structure and dynamics of simple hydrocarbon molecules on metal surfaces is of great importance in catalysis. The studies of surface species formed upon initial adsorption and their reaction at various conditions require understanding chemistry well enough to allow tailoring catalyst–support systems for specific reaction pathways. Most of the NMR techniques used in these studies have already been described in previous sections. The identification of adsorbed species can be performed by using a variety of NMR techniques:

1. Studies of ^{13}C NMR shifts in the spectra acquired at variable temperatures via direct polarization of ^{13}C nuclei (Bloch decay) or by ^1H – ^{13}C CP, with or without MAS and ^1H decoupling, are prevalent. The CP MAS technique is most useful when chemical shifts are good fingerprints of the adsorbed species. The additional advantage of the CP technique is that it can be used to discriminate between different carbon atoms on the basis of the strength of their dipolar interactions with protons. The dipolar dephasing experiment and the recently proposed spectral editing CP sequences allow distinguishing between various CH_n ($n = 0, 1, 2, 3$) carbon resonances (see *Spectral Editing Techniques: Hydrocarbon Solids*). However, considerable uncertainties often exist regarding identification of surface-bound species based on the ^{13}C shifts because of the potential complication of Knight shift dominance and the previously discussed heterogeneous broadening of resonances. The easiest approach of assuming direct correspondence to ^{13}C shifts observed in organometallic species in solutions may be applicable for surface species on ruthenium and rhodium, that exhibit negligible Knight shift, but is highly questionable on platinum and palladium,²⁷ for example.
2. When the isotropic chemical shifts of ^{13}C (or ^1H) fail to provide diagnostic fingerprints of the structures of the species chemisorbed on metals, dipolar couplings are often used to obtain information that is quite distinct from chemical shift data. For instance, ^{13}C – ^{13}C and ^{13}C – ^1H dipolar couplings can be measured by using spin echo and SEDOR techniques, respectively. The spin echo (slow beat) technique allows determination of the ^{13}C – ^{13}C bond length in hydrocarbon molecules as well as the fraction of ^{13}C nuclei that are not bound in pairs. The utility of the SEDOR technique, on the other hand, relies mainly on its ability to measure the fraction of ^{13}C nuclei which are bonded to hydrogen.
3. Multiple quantum (MQ) NMR provides another characteristic of a nuclear spin system that is supplied by dipolar coupling between spin- $\frac{1}{2}$ nuclei and that relates to the densities of protons on the catalyst surface. In short, MQ

NMR allows measurement of the numbers of strongly coupled spins in solids (see also *Multiple Quantum NMR in Solids*).

4. Deuterium NMR is increasingly used to probe the functional groups in surface species. The spectra of ^2H exhibit singularities that are characteristic of the configuration and motion of interacting spin systems and can be used to identify rigid C–D bonds, and rotating CD_3 groups, for example.

A considerable number of catalytic reactions have been studied over the last few years in several laboratories by using the above techniques. Since the results of these studies generally depend very strongly on the preparation of the catalyst (dispersion, reduction, and cleaning procedure) and the reaction conditions (adsorbate loading and temperature) it is not surprising that disparate results were reported for seemingly similar catalytic systems. In the following paragraphs I briefly review some representative studies, most of which involve the adsorption of ethene (C_2H_4). This process has been studied with particular interest because of the importance of the ethene-derived intermediates in cracking, hydrogenation, and hydrogenolysis reactions. ^{13}C techniques described in this section have also been used in the studies of CO hydrogenation on supported metal catalysts.³⁴

The CP MAS technique was first used to investigate the adsorption and reaction of ^{13}C enriched acetylene (C_2H_2) on Ru/SiO_2 and C_2H_4 on SiO_2 - and Al_2O_3 -supported platinum catalysts.^{28,35} Samples for these studies were reduced and dosed with adsorbates in NMR tubes attached to a vacuum line. After sealing, the catalysts were spun in a MAS system at 2.5 kHz. The CP MAS spectra required $1\text{--}8 \times 10^5$ cross polarizations and exhibited rather broad features that were assigned on the basis of the observed shifts and the results obtained using dipolar dephasing. The spectra for clean Pt/SiO_2 catalysts indicated that π -bonded C_2H_4 was the dominating surface species. In the presence of Cl^- or when Al_2O_3 was used as a support, the catalysts were more reactive, and the detected species included alkyl groups and σ -vinyl groups, or σ -diadsorbed species with a $\text{C}=\text{C}$ bond. The presence of ethylidyne (CCH_3) on platinum was excluded in this study.

In another investigation of C_2H_4 on a $\text{Pt/Al}_2\text{O}_3$ catalyst, broadband NMR of ^2H and ^{13}C was used to monitor structural changes brought about by heating.³⁶ Following adsorption at 253 and 297 K, the deuterium spectra were measured using a quadrupolar echo sequence. Two types of quadrupolar powder pattern exist with widths between singularities of 130 and 41 kHz, which are characteristic of static C–D bonds and rapidly rotating CD_3 groups, respectively. The ^{13}C spectra, acquired by using CP and proton decoupling, consisted of superimposed broad Gaussian lines that were interpreted with the aid of dipolar dephasing and variable contact time CP measurements. The results of ^2H and ^{13}C NMR demonstrated that below room temperature π -bonded C_2H_4 was formed on platinum and was partly converted to ethylidene (CHCH_3) at about 300 K. Upon further heating, CHCH_3 decomposed into methane gas and surface carbon.³⁶ In a similar study, a conversion of vinylidene (CCH_2) and hydrogen to CCH_3 on $\text{Pt/Al}_2\text{O}_3$ catalysts was postulated and monitored via ^2H NMR.³⁷ The progress of the conversion reaction was monitored by measuring the intensities of methyl groups in ^2H NMR spectra (taken at 77 K) as a function of annealing

temperature. The data were then analyzed by means of a set of differential rate equations describing H–D exchange for CCH_2 , conversion of CCH_2 to CCH_3 , and H–D exchange for CCH_3 , yielding the activation energy for conversion of $38.9 (\pm 10.5) \text{ kJ mol}^{-1}$. This analysis also demonstrated that the hydroxyl groups of the support served as an additional source of hydrogen in this reaction.

A variety of transient techniques in the NMR of ^{13}C , including variable temperature CP MAS, were used in a study of decomposition and reaction of ^{13}C -enriched ethene on Ru/SiO_2 catalysts.^{38,39} Figure 12 shows the CP MAS, ^1H -decoupled spectra taken 1, 7, and 30 days after the adsorption of C_2H_4 at room temperature. The narrow resonances in the spectra represent species of high mobility ($\tau_c < 10 \mu\text{s}$) that are not rigidly broadened only slightly in the absence of MAS and decoupling and could be easily assigned on the basis of chemical shifts, J splittings, and relative peak intensities at various conditions. (In the absence of paramagnetic adsorption sites, the shift deviations from the values determined in the liquid state are primarily due to bulk susceptibility and van der Waals interactions, and in most cases are not expected to exceed 2 ppm.) The following reaction products were identified in the spectra shown in Figure 12: peak (1) is a superposition of the CH carbon atoms of *trans*- and *cis*-2-butene; peak (2) represents the CH_2 carbon atom of butane; peak (3) is a CH_3 group of *trans*-2-butene; peak (4) is a CH_3 group in butane and *cis*-2-butene; and peak (5) originates from ethane.³⁸ The underlying broad features in the spectra represent species chemically bound to the ruthenium that could not be removed through evacuation [see Figure 12(d)]. Although MAS and strong ^1H -decoupling led to a considerable reduction of their linewidth, a severe inhomogeneous line broadening remained. The high-frequency peak centered at about 85 ppm was assigned to acetylide (CCH), although a small contribution to that peak at about 130 ppm due to the vinyl group (CHCH_2) could not be excluded. These assignments were based on chemical shifts and the CP MAS experiments performed with dipolar dephasing and variable contact times, which indicated that a significant fraction of carbon atoms contributing to the high-frequency peak had no directly bonded hydrogen. The resonances at 0–40 ppm were assigned to various surface-attached alkyl groups. Although high mobility did not preclude cross polarization of weakly adsorbed species, direct excitation of ^{13}C nuclei was necessary for quantitative analysis of the observed resonances. The results of intensity measurements indicated that there was approximately one chemisorbed carbon atom per surface ruthenium atom in the sample. Furthermore, the spectra taken for a series of samples sequentially dosed with ^{13}C -labeled and unlabeled ethene showed that the strongly adsorbed species resonating at 85 ppm was not appreciably consumed in the formation of reaction products.³⁸ Similar ^{13}C NMR studies were extended to low ($< 90 \text{ K}$) and high (up to 700 K) temperatures and provided a coherent picture of the chemistry of this relatively complex system.

The concepts involved in the production and detection of n -quantum coherences in NMR and their applications to the studies of protons on surfaces have been recently described by Gerstein et al.⁴⁰ In catalysis, the technique has been used to study the structure of C_2H_2 on platinum.⁴¹ In this work, the SEDOR experiment was first performed and yielded

Figure 12 ^{13}C CP MAS spectra of surface species on an Ru/SiO_2 catalyst at 300 K taken 1 day (a), 7 days (b), and 30 days (c) after ethene adsorption at room temperature. Spectrum (d) represents a sample that had been exposed to 13.3 kPa of C_2H_4 at 300 K for 15 min and then evacuated for 10 min. Each spectrum is a result of 150 000 cross polarizations taken with a contact time of 2 ms. (Reproduced by permission of the American Chemical Society from M. Pruski, J. C. Kelzenberg, B. C. Gerstein, and T. S. King, *J. Am. Chem. Soc.*, 1990, **112**, 4232)

several possible models for the composition of the adsorbed species. The final determination of the adsorbed structures ($77 \pm 7\%$ CCH₂ and $23 \pm 7\%$ HCCH) was made by measuring the amplitudes of 1-, 2-, and 3-quantum coherences as a function of C₂H₂ concentration. In another study, the use and limitations of MQ spin counting were tested by probing intermediates in the reaction of C₂H₄ on supported ruthenium.⁴² The maximum MQ coherence of $k_{\max} = 5$, corresponding to $n_{\max} = 6$ coupled protons, was observed after the catalyst reacted with C₂H₄ at 300 K for 1 h, was evacuated to 26×10^{-6} Pa, and sealed. The possible strongly bound C_mH_n fragments postulated in this work involved the metallocyclic intermediate Ru-CH₂-CH=CH-CH₂-Ru. This result was consistent with the finding that butenes were among the observed products in this reaction.³⁸ The limitations of the MQ technique are imposed by the background from protons in the support (which can be partly eliminated by deuteration⁴¹), the difficulties in extracting information about the distribution of sizes of the proton clusters, and possible intermolecular interference in the development of n -quantum coherences.

The spin echo technique was used to measure the ¹³C-¹³C internuclear distance (carbon-carbon bond length) in a number of systems. For example, the ¹³C-¹³C bond length of C₂D₂ on osmium, iridium, and platinum was found to be 0.144 (± 0.002) nm, whereas C₂H₄ on the same metals had a carbon-carbon bond length of 0.149 (± 0.002) nm.⁴³ It is preferable to perform the bond length measurements in systems with a single type of intact ¹³C-¹³C pair, although the bond scission between carbon atoms can also be measured with the spin echo method. To obtain a more complete picture of the surface chemistry, the spin echo technique can be used in conjunction with ¹H-¹³C SEDOR measurements. For example, after simultaneously observing ¹³C-¹³C bond scission and a fraction of ¹³C nuclei with carbon-hydrogen bonds at various reaction temperatures, the proposal was made that dehydrogenation preceded the decomposition of C₂ surface species on platinum.⁴³

6 CONCLUSION

This article has demonstrated the enormous potential of solid state NMR in the field of surface science. The choice of experimental methods for successful NMR studies of catalytic chemistry is critically important, but not always obvious. Undoubtedly, further collaboration between NMR spectroscopists, chemists, and chemical engineers will bring new and exciting advances in this fast evolving area of surface science.

1 INTRODUCTION

Measurements of ^{51}V NMR spectra of solids (see *Quadrupolar Nuclei in Glasses; Quadrupolar Nuclei in Solids*) with the use of modern NMR spectrometers (see *Spectrometers: A General Overview*) equipped with line-narrowing techniques for obtaining high-resolution spectra of solids (see *Double Rotation; High Speed MAS of Half-Integer Quadrupolar Nuclei in Solids; Magic Angle Spinning; Variable Angle Sample Spinning*) provide important information on the local environment of V nuclei.¹ The latter is known to be a key factor determining the activity and selectivity of heterogeneous catalysts. Due to this fact ^{51}V NMR solid state spectroscopy is successfully used for the studies of vanadia-based catalysts. The latter are used for the production of sulfuric acid, the selective oxidation of hydrocarbons, and also for reduction of atmospheric pollution.²

The results presented below show that ^{51}V NMR provides important information concerning the structure and reactivity of surface V sites. Herein will be discussed the main features of ^{51}V NMR in solids and its application for the studies of vanadium catalysts.

The vanadium-51 nucleus (natural abundance 99.76%) has a spin $I = \frac{7}{2}$, its electric quadrupole moment being $-4 \times 10^{-2} \times 10^{-24} \text{ cm}^2$; the relative intensity of ^{51}V NMR is 0.38 compared with an equal number of protons.

In general, three different types of interactions influence the ^{51}V NMR spectra of solid diamagnetic samples (see *Internal Spin Interactions and Rotations in Solids*): (1) the dipole interaction (see *Dipolar and Indirect Coupling Tensors in Solids*) of the magnetic moment of the ^{51}V nucleus with the magnetic moments of other nuclei that broadens the lines; (2) the quadrupole interaction (see *Quadrupolar Interactions*) of the ^{51}V nucleus with the electric field gradient that splits the lines and contributes to the shift of the central ($m_I = \frac{1}{2} \leftrightarrow m_I = -\frac{1}{2}$) line; and (3) the chemical shielding interaction (see *Chemical Shift Tensors*) that changes the position of the lines and makes them asymmetric.

In general, the lineshape might be rather complicated due to the simultaneous action of all types of interactions. For

powdered samples (the case typically met in heterogeneous catalysts) only the central transition ($m_I = \frac{1}{2} \leftrightarrow m_I = -\frac{1}{2}$) can most commonly be observed, while other transitions are too broad to be recorded. The line from the central transition is typically anisotropic, i.e. it has a rather complicated shape. This complicated shape reflects the fact that the observed line is actually a superposition of individual lines from vanadium sites having various orientations with respect to the external magnetic field. When these individual lines are narrow enough, the positions of the so-called discontinuity points can be readily identified in the overall ^{51}V NMR spectrum. From the position of the discontinuity points one can easily obtain the quadrupole coupling constant, χ , the asymmetry parameter, η , and the shielding anisotropy parameters σ_{11} , σ_{22} , and σ_{33} .³

Unfortunately, in the ^{51}V NMR spectra of many solid catalysts the effects from the discontinuity points are often completely or partially obscured due to the large broadening of individual lines. In this case computer analysis of the spectra recorded at various frequencies becomes necessary if one wishes to obtain the above-mentioned values. Note, that interactions affecting ^{51}V NMR spectra exhibit different frequency dependences. Indeed, the dipole interaction and the first-order quadrupole interaction do not depend on the spectrometer frequency ν_0 , while the second-order quadrupole effects are inversely proportional to ν_0 . The effects of the shielding anisotropy are directly proportional to ν_0 . Thus, at a sufficiently high ν_0 , the second-order quadrupole effects are suppressed and can be neglected, while the effects of the chemical shielding anisotropy become more pronounced and can be measured more precisely (*Chemical Shift Tensor Measurement in Solids*). A comparison of ^{51}V NMR spectra recorded at various ν_0 with computer simulated spectra has been demonstrated to allow sufficiently precise measurements of the spectral parameters characterizing vanadium sites in the solid catalysts.¹

Typical examples of computer simulated ^{51}V NMR spectra of V(V) sites in solid V_2O_5 are presented in Figure 1. Calculations were performed using the program for high magnetic fields ($B_0 > 7 \text{ T}$) when the perturbation theory approach can be applied, i.e. the values of the quadrupole and nuclear shielding terms are small when compared with the nuclear Zeeman energy.^{1,4}

Figure 1(a) and (b) show the influence of the first-order quadrupole effects on the calculated spectra of solid V_2O_5 at $\nu_0 = 105.15 \text{ MHz}$. Figure 1(c) demonstrates the spectral broadening in powdered or polycrystalline samples due to the distribution of quadrupole coupling constant.

2 VANADIUM-51 NMR SPECTRA OF SOLIDS WITH A WELL-CHARACTERIZED STRUCTURE. INTERRELATION BETWEEN ^{51}V NMR PARAMETERS AND THE LOCAL ENVIRONMENT OF V NUCLEI

To analyze the spectra of real catalytic systems one needs information on the spectra of vanadium compounds that might be present in the catalysts, as well as data on the interrelation between ^{51}V NMR parameters and the characteristics of the local environment of the V nuclei.

Figure 1 Computer simulated ^{51}V NMR spectra demonstrating the influence of the first-order quadrupole effects and line broadening on the spectra of solid V_2O_5 (at the frequency 105.15 MHz). The following parameters were used: $\chi = 0.805$ MHz, $\eta = 0.04$; $\sigma_{11} = 310$, $\sigma_{22} = 1280$, $\sigma_{33} = 270$ ppm. (a): The lineshape for the central transition ($\frac{1}{2}$, $-\frac{1}{2}$). (b) (Dotted lines): the lineshapes for all possible transitions: 1 ($-\frac{5}{2}$, $-\frac{7}{2}$), 2 ($-\frac{3}{2}$, $-\frac{5}{2}$), 3 ($-\frac{1}{2}$, $-\frac{3}{2}$), 4 ($\frac{1}{2}$, $-\frac{1}{2}$), the central transition, 5 ($\frac{3}{2}$, $\frac{1}{2}$), 6 ($\frac{5}{2}$, $\frac{3}{2}$), 7 ($\frac{7}{2}$, $\frac{5}{2}$). (b) (Solid line): the overall spectrum from all transitions. (c): Spectrum demonstrating the broadening of the lines from all transitions [dotted lines, numbered exactly as in (b)] and the overall spectrum from all transitions (solid line) due to the Gaussian distribution of quadrupole coupling constant χ . Dipolar linewidth $DF = 1.5$ kHz

The ^{51}V NMR spectra of various solid vanadium compounds^{1,3, 5–8} with well-characterized structures⁹ and of the vanadates of alkali metals, which are often used for the preparation of catalysts, have been studied.

In Table 1 the ^{51}V NMR chemical shielding parameters^{1,3,5,7,8} for vanadates are listed.

The ^{51}V NMR parameters of the large number of V compounds with a well-characterized crystal structure presented

in Table 1 prove the high sensitivity of NMR spectra toward details of the local environment of V nuclei.

In most cases the shape of ^{51}V NMR spectra measured in high magnetic fields ($B_0 > 7$ T) depends on the anisotropy of the chemical shielding tensor. The influence of the second-order quadrupole effects is typically smaller and often is quite negligible.¹⁰

The following conclusions on V coordination (tetrahedral or octahedral, regular or distorted) and the extent of association of vanadium–oxygen polyhedra can be drawn based on the type and magnitude of the chemical shielding anisotropy.^{1,7,10}

- For vanadium in regular tetrahedral sites (sites of the Q^0 type), the isotropic spectra with close values of the chemical shielding tensor components ($\sigma_{11} \approx \sigma_{22} \approx \sigma_{33}$) typically have $\Delta\sigma < 100$ ppm.
- For vanadium in slightly distorted tetrahedral sites with adjacent VO_4 tetrahedra sharing one common oxygen atom (sites of the Q^1 type), a fully anisotropic shielding tensor ($\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$) is typical, but with a larger $\Delta\sigma$ value ($\Delta\sigma = 70\text{--}300$ ppm).
- For vanadium in strongly distorted tetrahedral sites with adjacent VO_4 tetrahedra sharing two common oxygen atoms (sites of the Q^2 type), a fully anisotropic shielding tensor ($\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$) is typical with $\Delta\sigma = 300\text{--}375$ ppm.
- For vanadium in distorted octahedral sites (i.e. in a distorted octahedral environment of oxygen atoms), a nearly axial shielding anisotropy is typical with $\sigma_{11} \approx \sigma_{22} < \sigma_{33}$ ($\Delta\sigma = 450\text{--}900$ ppm for structures 4 in Figure 2 and $\Delta\sigma = 900\text{--}1300$ ppm for structures 5 in Figure 2).

Conclusions (a) to (d) are illustrated in Figure 2 for a family of Ti vanadates and V_2O_5 .

Note, that ^{51}V NMR spectra with approximate axial symmetry of the σ tensor should also be expected for VO_4 tetrahedra with symmetry close to C_{3v} , i.e. when one V–O bond differs significantly from the other three (which have about the same length) (sites of the Q^1 type). In this case the direction of $\sigma_{\parallel}$ will coincide with the direction of the V–O bond which differs from the three others, with $|\sigma_{\perp}| < |\sigma_{\parallel}|$ if this bond is shorter than the three others and $|\sigma_{\perp}| > |\sigma_{\parallel}|$ if this bond is the longest one.

A comparison of the shielding anisotropy $\Delta\sigma = |\sigma_{33} - \frac{1}{2}(\sigma_{11} + \sigma_{22})|$ for metavanadates whose structural data are known shows a good correlation between $\Delta\sigma$, on the one hand, and the angle $\text{O}_3\text{--V--O}_3'$ on the other hand [Figure 3(a)]. According to the structures of the metavanadates schematically presented in Figure 3(a) this angle characterizes the distortion of the tetrahedral environment of V. The larger the deviation of angle $\text{O}_3\text{--V--O}_3'$ from that in the regular tetrahedron ($109^\circ 28'$), the larger is $\Delta\sigma$.

Distortion of the VO_4 tetrahedra also results in an increase in the electric field gradient on the V nucleus. It seems natural to expect a correlation between $\Delta\sigma$ and the quadrupole interaction parameters, χ and η . Indeed, such a correlation has been found for metavanadates [Figure 3(b)].

In contrast to ^{27}Al ¹¹ and ^{29}Si ¹² (see *Aluminum-27 NMR of Solutions; Molecular Sieves: Crystalline Systems; Silicon-29 NMR*), the isotropic chemical shifts σ_{iso} for ^{51}V nuclei in vanadates are not too sensitive to V coordination (octahedral or tetrahedral). Compounds with rather different coordination may have very close σ_{iso} values. Thus, for vanadates, the anisotropy of the ^{51}V chemical shift is much more sensitive

to the character of the local arrangement of oxygen atoms around V than the isotropic chemical shift σ_{iso} . At the same time, for compounds with the same type of first coordination sphere, σ_{iso} depends notably on the type of atoms in the second coordination sphere of V, as also found for ²⁷Al and ²⁹Si atoms.^{11,12}

3 STUDY OF VANADIUM CATALYSTS

Typically, other techniques and approaches are used for identification of individual surface V species, in addition to ⁵¹V NMR. These include studies with magic angle spinning (MAS), NMR of nuclei of elements other than V and other spectroscopic methods, as well as chemical approaches. A combination of spectroscopic data with the measurements of catalytic activity allows one to identify the catalytically active sites.

3.1 V₂O₅/SiO₂ Catalysts

3.1.1 Prepared by Impregnation

Spectra of V₂O₅/SiO₂ samples prepared via impregnation of SiO₂ with NH₄VO₃ solution are presented in Figure 4. The

spectrum of the sample dried at 120 °C indicates only a slight change in the vanadium surroundings in comparison to that in NH₄VO₃ (spectrum 1a) and can be ascribed to (VO₄) species adsorbed on the SiO₂ surface. Calcination in vacuum provides a species that may differ both in the number of bonds with the surface and with neighboring vanadium species (spectra 2, 3, and 4 in Figure 4). Thus, lines present in spectra 2, 3, and 4 (calcination at 200 °C, 500 °C, and 700 °C) may be assigned to V species bonded to the surface via one, two, or three V–O bonds, respectively, as well as to V species bonded to neighboring vanadium species via one or two bonds.

Spectra of samples with high V concentrations (spectra 5 and 6) suggest the formation of the amorphous (nonregular) precursor of V₂O₅, since no sidebands are observed in the MAS spectra of these samples. Increasing the treatment temperature up to 700 °C results in the appearance of a line with highly resolved sidebands, due to rearrangement of the amorphous V₂O₅ structure to the crystalline one.

3.1.2 Prepared by VOCl₃ Interaction With SiO₂

The spectrum of the sample after VOCl₃ deposition suggests the presence of physically adsorbed VOCl₃ (narrow line with $\delta = -6$ ppm) and of VOCl_{3–n}(OSi)_n species bonded with the SiO₂ surface [a line with an axial anisotropy, Figure 4(b),

Figure 2 Relationship between the type of V coordination (tetrahedral or octahedral), the extent of polyhedra association (Q), and the shielding anisotropy $\Delta\sigma$. [As an example, the ^{51}V NMR spectra of Ti vanadates and V_2O_5 are presented: 1, Ti_3VO_4 (regular tetrahedra, Q^0); 2, $\text{Ti}_4\text{V}_2\text{O}_7$ (slightly distorted tetrahedra, Q^1); 3, TiVO_3 (strongly distorted tetrahedra, Q^2); 4, $\text{Ti}_2\text{V}_6\text{O}_{16}$ (distorted octahedra); 5, V_2O_5 (strongly distorted octahedron or square-pyramid)]

Figure 3 (a) Schematic representation of the structure of metavanadates of Na, Tl, Cs, Rb, and K and the dependence of the shielding anisotropy ($\Delta\sigma$) of their ^{51}V NMR spectra upon the $\text{O}_3\text{-V-O}_3'$ angle. This angle characterizes the distortion of the VO_4 tetrahedron from the regular form where $\text{O}_3\text{-V-O}_3' = 109^\circ 28'$. (b) Correlation between the shielding anisotropy $\Delta\sigma$ (data of Table 1) and the quadrupole coupling parameters χ and η (the latter taken from Pletnev et al.³ and Eckert and Wachs⁷) for metavanadates

Figure 4 (a) ^{51}V NMR spectra of $\text{V}_2\text{O}_5/\text{SiO}_2$ samples prepared via impregnation of SiO_2 with NH_4VO_3 (pH 7, 2.6 wt.% V_2O_5) 1, after treatment in vacuum at 120°C ; 2, at 200°C ; 3, at 500°C ; 4, at 700°C . Spectra 5 and 6 correspond to samples with a V content of 5.5 and 6.4 wt.% V_2O_5 , respectively, calcined at 500°C . (b) ^{51}V NMR spectra of $\text{VOCl}_3/\text{SiO}_2$ samples prepared by interaction of VOCl_3 from the gas phase with SiO_2 : 1, after VOCl_3 deposition; 1a, MAS spectrum of the same sample [line at 6 ppm corresponds to physically adsorbed VOCl_3 , anisotropic line with $\sigma_{\text{iso}} = 290$ ppm corresponds to $\text{VOCl}_2(\text{OSi})$ surface species]; 2, 3, 4, and 5, increase of H_2O content (replacement of Cl atoms to OH groups takes place during the first stage of hydration, then interaction of V species with the next H_2O molecules occurs); 6, spectrum 5 after evacuation at 100°C . All the spectra here and in the remaining figures were recorded at 105.15 MHz, pulse duration = $0.5\ \mu\text{s}$, pulse repetition frequency = 1 Hz. Chemical shifts are presented with respect to VOCl_3 as external reference

spectrum 1]. Deposition of VOCl_3 at room temperature yields complexes with $n = 1$ (a line with $\sigma_{\text{iso}} = 290$ ppm, spectrum 1a). Increasing the deposition temperature to 400°C leads to complexes with $n = 2$ or 3 . The first additions of water cause the disappearance of physically adsorbed VOCl_3 [Figure 4(b), spectrum 2], then water interacts with the $\text{VOCl}_{3-n}(\text{OSi})_n$ surface species producing partially hydrated $\text{VO}(\text{OH})_y\text{-Cl}_{3-n-y}(\text{OSi})_n$ ($y \leq n$, $n = 1, 2$, or 3) species (spectra 2 and 3) and fully hydrated $\text{VO}(\text{OH})_{3-n} \cdot 2\text{H}_2\text{O}(\text{OSi})_n$ species (for these species the sign of the anisotropy is opposite to that for species containing Cl in their coordination sphere, $\sigma_{\parallel} > \sigma_{\perp}$). Dehydration under mild conditions (100°C) results in the removal of water from the first coordination sphere and in the formation of associated tetrahedral complexes (spectrum 5). The latter was ascribed to $\text{VO}(\text{OSi})_3$ by Das et al.¹³

Application of magic angle spinning does not improve the resolution, unlike the situation when complexes contain Cl in the first coordination sphere. This indicates a nonregularity in the structure of the surface oxide complexes.

These data along with results presented by Lapina et al.¹⁴ show that after calcination at $400\text{--}500^\circ\text{C}$ similar complexes are formed on the SiO_2 surface by the different deposition procedures.

3.2 $\text{V}_2\text{O}_5/\text{Al}_2\text{O}_3$ Catalysts

Vanadium-51 NMR spectra of $\text{V}_2\text{O}_5/\text{Al}_2\text{O}_3$ catalysts prepared by interaction of Al_2O_3 with VOCl_3 , impregnation of Al_2O_3 with NH_4VO_3 , and ultra-high-intensity grinding (UHIG) of $\text{V}_2\text{O}_5\text{-Al}_2\text{O}_3$ mixtures are shown in Figures 5 and 6.

3.2.1 Prepared by Impregnation

The various ^{51}V NMR spectra of these catalysts can be classified in terms of the five different types of lines contained^{15,16} (Figure 5). Line A [spectrum (a)-1] observed for wet samples of low V content (1 wt.%) has been attributed to tetrahedral VO_4 species relatively loosely bound to the Al_2O_3 surface via one or two oxygen atoms. Line B, which was detected for calcined samples of low V content (1 wt.%) [spectrum (a)-2] was attributed to VO_4 tetrahedra bound more firmly to the Al_2O_3 surface via two or more oxygen atoms. Line C observed for samples with a large V content either dried or calcined [spectrum (a)-3] has been attributed to polynuclear V species of the decavanadate type on the Al_2O_3 surface. Line D is attributed to the AlVO_4 phase. It has been detected in calcined samples with a large V concentration [spectrum (a)-4]. From the MAS spectra, the σ_{iso} values for each of the three nonequivalent V sites in the structure of this compound were as follows: $\sigma_{\text{iso}1} = 668 \pm 5$; $\sigma_{\text{iso}2} = 747 \pm 5$; $\sigma_{\text{iso}3} = 780 \pm 5$ ppm. Line E ($\sigma_{\perp} = 310$ ppm, $\sigma_{\parallel} = 1270$ ppm) relates to V_2O_5 [spectrum (a)-5]. In the spectra of real catalysts, superposition of lines from different V sites occurs as shown in Figure 5(b).

3.2.2 Prepared by Interaction of Al_2O_3 With VOCl_3

Figure 6(a) shows that at least four types of particles are formed on the Al_2O_3 surface after VOCl_3 deposition: physically adsorbed VOCl_3 (narrow line with $\delta \approx 0$ ppm) and particles containing Cl atoms in the first coordination sphere,

i.e. $\text{VOCl}_{3-n}(\text{OAl})_n$, where $n = 1, 2$, or 3 (broad lines in the range from 0 to -1000 ppm, spectrum 1). The process of hydration occurs initially by hydration of the physically adsorbed VOCl_3 (disappearance of the signal at $\delta \approx 0$ ppm) and then exchange of Cl atoms in the first coordination sphere of V by OH groups takes place; after sample treatment at 500°C , the formation of V sites typical for catalysts prepared by impregnation are also formed [cf. Figure 6(a), spectrum 5 and Figure 6(b), spectrum 3].

3.2.3 Prepared by UHIG Treatment

The ultra-high-intensity grinding (UHIG) of $\text{V}_2\text{O}_5\text{-Al}_2\text{O}_3$ mixtures was found to induce a heterogeneous chemical reaction between these oxides producing highly dispersed V species on the support surface.¹⁷ The ^{51}V NMR spectrum of V_2O_5 after UHIG treatment demonstrates the broadening of the peaks from first-order quadrupole effects due to distortion of the local vanadium environment while the general crystal structure of V_2O_5 is retained [spectra 1 and 2 in Figure 6(c)]. Only a small part of the V_2O_5 reacts with Al_2O_3 when a $\text{V}_2\text{O}_5\text{-Al}_2\text{O}_3$ mixture is calcined for 14 h at 500°C (peak at -570 ppm) (spectrum 3). A more complete interaction between V_2O_5 and Al_2O_3 takes place in the samples after UHIG treatment at room temperature (spectrum 4). As the concentration of V increases, the other tetrahedral V state (peak near -750 ppm) appears. Subsequent calcination at 500°C produces V in octahedral coordination. In general, ^{51}V NMR spectra of the samples treated at 500°C after UHIG treatment show the formation of surface structures that are similar to those for $\text{V}_2\text{O}_5/\text{Al}_2\text{O}_3$ catalysts prepared by the conventional impregnation/calcination method.

Thus, the types of surface V species on Al_2O_3 are the same for all three preparation procedures discussed above. Their relative amounts depend in a similar way on the total V concentration on the Al_2O_3 surface and on the treatment temperature. At low V concentration species A prevail, while at the increased V concentration species B and C appear on the catalyst surface. At still larger amounts of supported V (>10 wt.%), V_2O_5 and AlVO_4 also form.

3.3 $\text{V}_2\text{O}_5/\text{MgO}$ Catalysts

Vanadium-51 NMR spectra of $\text{V}_2\text{O}_5/\text{MgO}$ catalysts, recorded at various vanadium content, show four different V sites on the MgO surface (Figure 7).¹⁸ Only one of them can be attributed to magnesium vanadate, $\text{Mg}_3(\text{VO}_4)_2$. Other V sites have been identified on the basis of correlations between the structure of the local environment of the V nuclei and the shielding anisotropy.

The narrow isotropic line with $\sigma_{\text{iso}} = 480$ ppm observed at low vanadium concentration (from 1.6–2.6 wt.% V) [spectra 1 and 2 in Figure 7(a)] has been attributed to isolated surface V atoms which have a virtually regular tetrahedral oxygen environment. Two broadened lines, i.e. an almost isotropic line with $\sigma_{\text{iso}} = 570$ ppm and a line with $\sigma_{\perp} = 510$ ppm, $\sigma_{\parallel} = 720$ ppm have been assigned to surface clusters with V atoms in a tetrahedral environment (spectra 2, 3, and 4). At large V content, orthovanadate $\text{Mg}_3(\text{VO}_4)_2$ ($\sigma_{\text{iso}} = 560$ ppm) is formed in the catalysts (spectrum 4). The calculated shapes of the individual lines for various V sites in $\text{V}_2\text{O}_5/\text{MgO}$ catalysts and

Figure 5 Classification of ^{51}V NMR lines observed in $\text{V}_2\text{O}_5/\text{Al}_2\text{O}_3$ catalysts prepared by Al_2O_3 impregnation with NH_4VO_3 solution. (a) Individual lines: 1, line A, $\sigma_{\text{iso}} = 520\text{--}590$ ppm, observed in wet samples at a V content from 1–2 wt.%; 2, line B, $\sigma_{\text{iso}} = 750$ ppm observed at a V content of 1 wt.% for samples calcined at 500°C ; 3, line C, $\sigma_{\perp} = 350$ ppm observed for wet samples at high V content; 4, line D from polycrystalline AlVO_4 ; 5, line E from polycrystalline V_2O_5 . (b) Spectra of various catalysts: 1, prepared by impregnation with NH_4VO_3 (pH 12, 2.2 wt.% V) dried at 110°C , superposition of lines A and B; 2, the same sample calcined at 550°C , superposition of lines A, B, and C; 3a, MAS spectrum of sample 3; 3, catalyst prepared via impregnation with VOCl_2 (pH 0.4, 14 wt.% V) calcined at 500°C , superposition of lines B, C, and D (line D gives well-resolved sidebands with MAS); 4, catalyst prepared via impregnation with NH_4VO_3 (pH 7, 14.8 wt.% V), the superposition of lines A, D, and E

Figure 6 Vanadium-51 NMR spectra of V_2O_5/Al_2O_3 catalysts at different stages in their preparation: (a) Catalysts prepared by interaction with gaseous $VOCl_3$: 1, spectrum after $VOCl_3$ deposition; 2, 3, and 4, increase of H_2O content; 5, sample 4 after calcination at $500^\circ C$. (b) Catalysts prepared by impregnation with NH_4VO_3 (pH 12, 3.8 wt.% V): 1, wet sample; 2, sample dried at $120^\circ C$; 3, sample calcined at $500^\circ C$. (c) Catalysts prepared by ultra-high-intensity grinding (UHIG): 1, V_2O_5 ; 2, V_2O_5 after UHIG; 3, $V_2O_5-Al_2O_3$ mixture (5 wt.% V_2O_5) calcined at $500^\circ C$ for 14 h; 4, after UHIG treatment at room temperature; 5, UHIG with subsequent calcination of the samples at $500^\circ C$ for 2 h

deconvolution of the experimental spectrum into individual lines are also shown in Figure 7(b) and (c). Figure 7(c) also presents the relative amounts of the various V species as measured by deconvolution of the experimental spectra.

Hence, the ^{51}V NMR spectra of V_2O_5/MgO catalysts allow one to form certain conclusions on the structure of surface V species and their concentration as a function of the total vanadium content.

3.4 V_2O_5/TiO_2 Catalysts

The influence of the admixtures on the structure of the supported species has been demonstrated for V_2O_5/TiO_2 supported catalysts^{1,19} (Figure 8). Spectra of catalysts prepared via the gas-phase reaction of $VOCl_3$ with TiO_2 followed by subsequent hydration and H_2O removal at $350^\circ C$ are shown in Figure 8(a). The catalyst prepared from the most pure anatase (impurities less than 0.1 wt.%) contains two tetrahedral (peaks at $\delta = -440$ and -560 ppm) and one octahedral species (peak at $\delta = -320$ ppm) as follows from spectrum 1 in Figure 8(a). An admixture containing sulfate anions (3.9 wt.%) increases the content of the octahedral vanadium species (spectrum 2). The presence of 3 wt.% Si leads to tetrahedral

vanadium complexes typical for V_2O_5/SiO_2 samples (peak at $\delta = -490$ ppm, spectrum 3) and with anatase containing Na (2.3 wt.%) the formation of Na_3VO_4 was observed (line with $\delta = -535$ ppm, spectrum 4). Similar surface species have also been identified for the same catalysts prepared by impregnation of the same anatase samples with a solution of vanadyl oxalate [cf. Figure 8(a) and (b)].

Thus, the type of surface V species on TiO_2 depends mainly on the presence of the impurities in anatase with the preparation procedure having a considerably smaller effect on the type of V sites on the catalyst surface.

Data analysis presented above and by Lapina et al.¹ shows that the structure of surface V species depends mainly on the type of support. The preparation procedure (impregnation, grafting, UHIG treatment) appears to have much less of an effect on the type of V sites on the catalyst surface provided that the concentration of vanadium and the treatment temperatures are the same.

At a V concentration less than 0.5 monolayer, surface tetrahedral species with different extents of distortion of the oxygen environment are formed, with the distortion depending on the type of the support used.

(a) For MgO and $AlPO_4$, the surface vanadium species has an almost regular tetrahedral environment with σ_{iso} depending

Figure 7 (a) ^{51}V NMR spectra of $\text{V}_2\text{O}_5/\text{MgO}$ catalysts of various vanadium content: 1, 1.6 wt.%; 2, 2.6 wt.%; 3, 5.0 wt.%; 4, 9.6 wt.%. The upper spectra were recorded without MAS; the MAS spectra are shown below. The isotropic chemical shifts are indicated by asterisks (*). (b) The simulated lineshapes of ^{51}V NMR spectra for various V species found in $\text{V}_2\text{O}_5/\text{MgO}$ catalysts: 1, isolated tetrahedral surface species; 2, tetrahedral surface clusters; 3, tetrahedral surface clusters of another type; 4, $\text{Mg}_3(\text{VO}_4)_2$. (c) Deconvolution of an experimental spectrum (2.6 wt.% V) into individual lines and the percentage of various V species on the MgO surface as a function of the total V content in $\text{V}_2\text{O}_5/\text{MgO}$ catalysts: 1, isolated tetrahedral surface species; 2, tetrahedral surface clusters; 3, tetrahedral surface clusters of another type; 4, $\text{Mg}_3(\text{VO}_4)_2$

on the type of support employed ($\sigma_{\text{iso}} = 480$ and 880 ppm for MgO and AlPO_4 , respectively) and $\Delta\sigma < 100$ ppm.

(b) For Al_2O_3 , ZrO_2 , $\text{ZrO}_2/\text{TiO}_2$, and SnO_2 , slightly distorted tetrahedral V species exist with σ_{iso} values ranging from 500 – 600 ppm and $\Delta\sigma < 200$ ppm.

(c) For SiO_2 and TiO_2 , distorted tetrahedral V species with one short V–O bond are formed. They exhibit axial anisotropy of chemical shielding with $\Delta\sigma < 600$ ppm.

An increase in V concentration (up to monolayer coverage) results in association of surface species. The following features associated with their ^{51}V NMR spectra can be noted.

(a) On MgO, AlPO_4 associated tetrahedral surface V species exhibit spectra with a fully anisotropic σ tensor, which points to a distortion of the VO_4 tetrahedra in these species ($\sigma_{\text{iso}} = 560$ – 570 ppm). The lines for such associated species are usually broader when compared with those for isolated species.

(b) For associated V species on Al_2O_3 , ZrO_2 , SnO_2 , and $\text{TiO}_2/\text{ZrO}_2$, fully anisotropic lines from distorted VO_4 surface tetrahedra are also observed ($\sigma = 700$ – 800 ppm). The widths of the lines are close to those for isolated V species on this surface.

(c) For associated V species on Al_2O_3 , ZrO_2 , $\text{TiO}_2/\text{ZrO}_2$, and SnO_2 of another type, lines with an axial anisotropy of the

shielding tensor arising from distorted octahedral V sites are observed ($\sigma_{\perp} = 320$ – 330 ppm, $\Delta\sigma = 600$ ppm).

(d) For associated V species on SiO_2 and TiO_2 , lines with an axial anisotropy of the shielding tensor arising from distorted octahedral V sites are observed ($\sigma_{\perp} = 290$ – 300 ppm, $\Delta\sigma > 900$ ppm).

A further increase of V concentration above monolayer coverage provides crystalline compounds [V_2O_5 on SiO_2 , TiO_2 , AlPO_4 , $\text{TiO}_2/\text{ZrO}_2$, and SnO_2 ; AlVO_4 on Al_2O_3 ; and $\text{Mg}_3(\text{VO}_4)_2$ on MgO].

Water adsorption changes the V coordination from tetrahedral to octahedral on SiO_2 and TiO_2 . In these cases, water molecules insert into the first coordination sphere of V. For V sites on ZrO_2 , AlPO_4 , $\text{TiO}_2/\text{ZrO}_2$, and SnO_2 , water molecules adsorb in the second coordination sphere, providing slight shifts of the ^{51}V NMR lines upon adsorption.

Addition of promoters, such as rhodium, titania, or zirconia (or impurities), results in notable changes in both the structure of the surface V species and their redistribution on the surface.

3.5 Vanadium Catalysts for SO_2 Oxidation

The active component of vanadium catalysts for SO_2 oxidation is known to consist of vanadium oxide and sulfates or pyrosulfates of alkali metals (K, Na, Cs are most commonly

Figure 8 Vanadium-51 NMR spectra of V_2O_5/TiO_2 catalysts (a) prepared by gas phase reaction of $VOCl_3$ with TiO_2 followed by subsequent hydration and removal of H_2O with a stream of He at $350^\circ C$ and (b) prepared via impregnation with a solution of VOC_2O_4 : 1, anatase (all impurities less 0.1 wt.%); 2, TiO_2 (3.9 wt.% SO_4); 3, TiO_2 (3 wt.% Si); 4, TiO_2 (2.3 wt.% Na)

used) supported on porous materials such as silica or silica alumina. At ambient temperature the active component forms a thin vitreous film dispersed over the support. Under the reaction conditions ($400\text{--}500^\circ C$), the active component exists as a melt forming a very thin liquid layer on the support surface.

We present here the results of ^{51}V NMR studies of oxosulfatovanadates(V), chemical compounds formed between V_2O_5 and alkali pyrosulfates that are assumed to be present in the active component of these catalysts, as well as of $V_2O_5\text{--}K_2S_2O_7$ alloys and of commercial catalysts. Combined with other spectroscopic methods and kinetic studies, these results have helped to reveal the active sites in SO_2 oxidation and the mechanism of this catalytic reaction.^{1,20,21}

The spectra of oxosulfatovanadate(V) $K_3VO_2(SO_4)_2$, the alloy $V_2O_5 \cdot 3K_2S_2O_7$, and a commercial catalyst are presented in Figure 9. All oxosulfatovanadates(V) exhibit axial anisotropy of the chemical shielding tensor with parameters close to those for V_2O_5 . Thus the local environment of the vanadium atom in oxosulfatovanadates(V) is similar to that in V_2O_5 , where vanadium has a distorted octahedral (bipyramidal) oxygen atom environment with one V–O bond being considerably shorter than the others. Comparison of the spectrum of $V_2O_5 \cdot 3K_2S_2O_7$ alloy (Figure 9) with that for oxosulfatovanadate(V) $K_3VO_2(SO_4)_2$ shows that the former exhibits σ values close to those for oxosulfatovanadate(V). This indicates the same local environment for the V atoms in the glassy alloy and in crystalline oxosulfatovanadate(V).

The ^{51}V NMR spectra for various catalysts after treatment with a reaction gas mixture become quite similar and exhibit the same two lines, namely an almost isotropic line with $\sigma_{iso} = 520\text{--}560$ ppm and a line with axial anisotropy of the shielding tensor. Only the relative intensities of the

Figure 9 Vanadium-51 NMR spectra of (1) oxosulfatovanadate(V) $K_3VO_2(SO_4)_2$; (2) the solid alloy $V_2O_5 \cdot 3K_2S_2O_7$; (3) the industrial catalyst BAV before treatment under the reaction conditions; (4) the same after treatment

two lines but not their character vary from one catalyst to another. In particular, the average chemical shifts for both the isotropic and anisotropic lines ($\sigma_{\perp} = 320\text{--}350$ ppm, $\sigma_{\parallel} = 1200\text{--}1300$ ppm) are almost the same for all the catalysts studied. This indicates that the active component in these catalysts is the same and is actually formed during the course of catalytic reaction.² Initially, catalysts arising from different preparations contain a variety of V sites. However, on interaction with the components of the reaction media only the two sites mentioned above are formed. The nearly isotropic line belongs to V atoms in a slightly distorted tetrahedral environment and can be attributed to vanadium bonded to the support. This line exhibits an increase in relative intensity with a decrease in the overall V content of the sample. Thus, the isotropic line belongs to V complexes on the SiO_2 surface.

Measurement of the catalytic activity for a series of samples with different contents of surface tetrahedral V has showed the latter to be inactive in SO_2 oxidation.²⁰

To elucidate the nature of the vanadium complexes which are active in SO_2 oxidation, ^{51}V , ^{17}O , ^{23}Na , ^{39}K , and ^{133}Cs NMR were combined with catalytic activity measurements of $V_2O_5\text{--}K_2S_2O_7$ melts and of catalysts with different amounts of the active component on SiO_2 .^{1,20,21}

Vanadium-51 NMR spectra of V_2O_5 and $V_2O_5 \cdot 3Cs_2S_2O_7$ alloy at temperatures below and above their melting points (Figure 10) demonstrate the spectrum of molten $V_2O_5 \cdot 3Cs_2S_2O_7$ (see *Molten Salts*) to be substantially broader than that of V_2O_5 . This means, that unlike V_2O_5 , where melting leads to a separation of the vanadium–oxygen layers and breaks them into relatively short fragments, in molten $V_2O_5 \cdot 3Cs_2S_2O_7$ substantially larger particles are formed.

Oxygen-17 NMR (see *Oxygen-17 NMR*) has also been used to characterize the melt of the active component in SO_2 oxidation at $500^\circ C$ in the presence of an $SO_3 + SO_2 + O_2$ mixture, i.e. under typical conditions for the catalytic process in industry.^{1,20,21} Addition of V_2O_5 to $K_2S_2O_7$ leads to a shift and a broadening of the ^{17}O line, indicating V coordination with pyrosulfate anions. A more sophisticated analysis using a thermodynamic model of the ^{17}O linewidths has shown that at small vanadium concentrations approximately two to three pyrosulfate anions are coordinated to one V atom.

Figure 10 Vanadium-51 NMR spectra of (a) V_2O_5 and (b) of the alloy $V_2O_5 \cdot 3Cs_2S_2O_7$ (1) below the melting point (i.e. at $20^\circ C$) and (2) above the melting point ($670^\circ C$ and $370^\circ C$ for (a) and (b), respectively). Above: the structures formed in molten V_2O_5 and $V_2O_5 \cdot 3Cs_2S_2O_7$ alloy

Oxygen-17 NMR data also suggest a fast exchange between terminal and bridging oxygen atoms in the pyrosulfate anion which may occur via the reaction $S_2O_7^{2-} \rightleftharpoons SO_4^{2-} + SO_3$. The characteristic time τ during which this equilibrium is established is less than 10^{-3} s. Oxygen-17 and ^{51}V NMR data show that on addition of V_2O_5 to $K_2S_2O_7$, complexes are formed according to the reaction: $V_2O_5 + 3K_2S_2O_7 \rightleftharpoons 2K_3VO(SO_4)_3$. The increase in the ^{51}V and ^{17}O linewidths on increasing the V concentration suggests a further association of the V species leading to larger oligomers of the type shown in Figure 10. The large size of these oligomers makes their rotational diffusion very slow. Internal rotation of their fragments can also be hindered because of branching and linking of the oligomeric chains. Because of these factors, the ^{17}O and ^{51}V NMR lines of these species are too broad to be detected.

When supported on SiO_2 , the dimeric or oligomeric vanadium species can be more stabilized on the surface due to their interaction with Si-OH groups. These results agree well with studies of the catalytic activity of thin films of active melts on Pyrex glass and on SiO_2 , as well as with kinetic studies of SO_2 oxidation.²⁰

It will be assumed that the reader is familiar with the NMR density matrix equation ¹ of a molecule given as

$$\dot{\hat{\rho}} = -i[\hat{\mathcal{H}}_{\text{spin}}^0 + \hat{\mathcal{H}}_{\text{rf}}, \hat{\rho}] + \hat{R}_{\text{op}}\hat{\rho} \quad (1)$$

where the relaxation operator $\hat{R}_{\text{op}}$ ² couples the spin system to the external world—sometimes referred to as the ‘bath’. We will show how equation (1) is modified to allow for chemical exchange.

1 DERIVATION OF THE EXCHANGE OPERATOR

The form of the exchange operator is derived using the ‘usual’ assumptions that: (a) exchange time τ_e is much longer than the correlation time τ_c used to obtain $\hat{R}_{\text{op}}$; and (b) exchange relaxation time is exponential. Consider an equilibrium exchanging system where two species, AB and CD, mutually exchange two different fragments, B with C, in a bimolecular collision. For reasons which become apparent later it is convenient to describe the molecules in terms of the fragments which exchange

The fragments A, B, C, and D can be single protons or more complex moieties. Throughout this presentation it is important to be aware that we are always dealing with molecular components which are in equilibrium.

The mean lifetime between exchanges τ_{sp} of each species involved in the equilibrium process is defined as the ratio of its rate of formation R_{ex} (or disappearance, they are the same) to its concentration (sp):

$$1/\tau_{\text{sp}} = R_{\text{ex}}/(\text{sp}) \quad (3)$$

Then the τ_e values for the different species are given by:

$$\left. \begin{aligned} 1/\tau_{\text{AB}} &= k_f(\text{DC}), & 1/\tau_{\text{CD}} &= k_f(\text{AB}), \\ 1/\tau_{\text{AC}} &= k_r(\text{BD}), & 1/\tau_{\text{BD}} &= k_r(\text{AC}) \\ k_f(\text{AC})(\text{BD}) &= k_r(\text{AC})(\text{BD}) \end{aligned} \right\} \quad (4)$$

We can pictorially rewrite the reaction in equation (2) as

to proceed via two intermediate bimolecular complexes, (1) before new bonds are formed, and (2) after rearrangement but before dissociation to products.

Let us concentrate on AB for the moment. The nuclear spin Hamiltonian of AB in the rotating coordinate system is

$$\hat{\mathcal{H}}^{\text{AB}} = \sum_s (\omega_{0s} - \omega) \hat{I}_s^z + \sum_{s,t} J_{s,t} \hat{I}_s \cdot \hat{I}_t + \omega_1 \sum_s \hat{I}_s^x \quad (6)$$

where for the moment we do not need to specify which spins belong to A and B. (Exchange for weakly coupled systems where $\hat{I}_s \cdot \hat{I}_t$ is replaced by $\hat{I}_s^z \hat{I}_t^z$ was developed by Gutowsky et al.³) The density matrix equation for AB in the rotating frame between collisions is given as (denoted by $\sim$)

$$\dot{\hat{\rho}}^{\text{AB}} = -i[\hat{\mathcal{H}}^{\text{AB}}, \hat{\rho}^{\text{AB}}] + \hat{R}^{\text{AB}}\hat{\rho} \quad (7)$$

(Note that material in this article up to Section 5 has been taken from the book by Kaplan and Fraenkel.⁴) Now rewrite equation (7) as

$$\dot{\hat{\rho}}^{\text{AB}} = -i(\hat{\mathcal{L}}_S^{\text{AB}} + \hat{\mathcal{L}}_R^{\text{AB}})\hat{\rho}^{\text{AB}} \quad (8)$$

where by comparison one sees that

$$\hat{\mathcal{L}}_S^{\text{AB}}\hat{\rho}^{\text{AB}} = [\hat{\mathcal{H}}^{\text{AB}}, \hat{\rho}^{\text{AB}}] \quad (9)$$

$$i\hat{\mathcal{L}}_R^{\text{AB}}\hat{\rho}^{\text{AB}} = \hat{R}^{\text{AB}}\hat{\rho} \quad (10)$$

We do this in order to make equation (8) appear as a conventional first-order differential equation. Next, equation (8) is integrated, with the initial condition that

$$\hat{\rho}^{\text{AB}}(t') = \hat{\rho}^{\text{AB}}(\text{col}, t') \quad (11)$$

where the right-hand side is the value of $\hat{\rho}^{\text{AB}}$ at time t' immediately after a collision which has resulted in the formation of an AB molecule. Note that the collision time is taken to be instantaneous on the NMR timescale.

The result is that

$$\hat{\rho}_{(t)}^{\text{AB}} = \exp[-i(\hat{\mathcal{L}}_S^{\text{AB}} + \hat{\mathcal{L}}_R^{\text{AB}})(t - t')]\hat{\rho}^{\text{AB}}(\text{col}, t') \quad (12)$$

The probability that after a time $t - t'$, AB will not suffer an exchange collision is, for exponential exchange relaxation,

$$\frac{\exp[-(t - t')/\tau_{AB}]}{\tau_{AB}} \quad (13)$$

and, therefore, the ensemble average $\hat{\rho}^{AB}(t)$ is the weighted probability of all AB molecules created at t' which survive until time t :

$$\begin{aligned} \hat{\rho}^{AB}(t) = & \int_{-\infty}^t \exp\{-[i(\hat{\mathcal{L}}_S^{AB} + \hat{\mathcal{L}}_B^{AB})(t - t')]\} \hat{\rho}^{AB}(\text{col}, t') \\ & \times \frac{\exp[-(t - t')/\tau_{AB}]}{\tau_{AB}} dt' \end{aligned} \quad (14)$$

We next differentiate equation (14) to obtain the differential form of the $\hat{\rho}^{AB}$ equation. This is done using the result from calculus that for

$$y(t) = \int_A^t g(t, t') dt' \quad (15)$$

$$\frac{dy}{dt} = \int_A^t \frac{d}{dt} [g(t, t')] dt' + g(t, t) \quad (16)$$

Applying equation (16) to equation (14), we obtain the result

$$\dot{\hat{\rho}}^{AB} = -i(\hat{\mathcal{L}}_S^{AB} + \hat{\mathcal{L}}_B^{AB})\hat{\rho}^{AB} + \frac{1}{\tau_{AB}}[\hat{\rho}^{AB}(\text{col}) - \hat{\rho}^{AB}] \quad (17)$$

or going back to the definitions of $\hat{\mathcal{L}}_S^{AB}$ and $\hat{\mathcal{L}}_B^{AB}$ in equations (9) and (10), we have

$$\dot{\hat{\rho}}^{AB} = -i[\hat{\mathcal{H}}^{AB}, \hat{\rho}^{AB}] + \hat{R}^{AB}\hat{\rho} + (1/\tau_{AB})[\hat{\rho}^{AB}(\text{col}) - \hat{\rho}^{AB}] \quad (18)$$

To abbreviate the exchange contribution in the density matrix equation, we write

$$\hat{E}\hat{\rho}^{AB} = (1/\tau_{AB})[\hat{\rho}^{AB}(\text{col}) - \hat{\rho}^{AB}] \quad (19)$$

where $\hat{\rho}(\text{col})$ will be evaluated in the following section.

1.1 Permutation of Indices Method

What remains is to evaluate $\hat{\rho}^{AB}(\text{col})$. We can do this in two ways. First, we can think backward in time, starting with $\hat{\rho}^{AB}(t)$ just after formation of AB by collision and ask what are its antecedents (AC and BD).⁴ Alternatively, one can think forward in time taking AC and BD before an exchange collision and take them through the chemical reaction. The latter was the first method suggested.⁵ However, the former is computationally, if not conceptually, the much simpler approach and the one we will use in this article. This ‘backward’ approach is simpler only if one works in the product representation.

The product representation is written as

$$\psi = \prod_{s=1}^n \phi_{ms} \quad (20)$$

where s labels the spins and ϕ_{ms} are eigenfunctions of $\hat{I}^z$:

$$\hat{I}_s^z \phi_{ms} = m_s \phi_{ms} \quad (21)$$

For $I = \frac{1}{2}$,

$$\phi_{1/2} = \alpha; \quad \phi_{-1/2} = \beta \quad (22)$$

and for a molecule made up of only half spins, a product wavefunction would have the form

$$\phi_{\text{molecule}} = \alpha_1 \beta_2 \alpha_3 \beta_4 \beta_5 \alpha_6 \cdots \quad (23)$$

The ‘product representation’ has a special utility because the exchange collision is assumed to happen so fast on the timescale of the nuclear spin Hamiltonian that the nuclear spin wavefunction is not changed by the collision. This is an example of the so-called ‘sudden approximation’ in quantum mechanics.⁶ Thus, the product wavefunction before and after the collision will be the same.

Now let us see how we make use of these ideas. A particular product wavefunction of molecule AB can be written as

$$\phi_{ab}^{AB} = \phi_a^A \phi_b^B \quad (24)$$

where ϕ_a^A and ϕ_b^B are the individual product wavefunctions of fragments A and B, respectively. An arbitrary matrix element of $\hat{\rho}^{AB}$ in the product representation just after an exchange collision can be written as

$$\langle ab | \hat{\rho}^{AB} | a'b' \rangle \quad (25)$$

Multiplying equation (25) by 1 in the form of

$$1 = \text{Tr} \hat{\rho}^{CD} = \sum_{cd} \langle cd | \hat{\rho}^{CD} | cd \rangle \quad (26)$$

equation (25) takes the form

$$\langle ab | \hat{\rho}^{AB} | a'b' \rangle = \sum_{cd} \langle ab | \hat{\rho}^{AB} | a'b' \rangle \langle cd | \hat{\rho}^{CD} | cd \rangle \quad (27)$$

During an exchange collision, there is a mutual reorganization where B is replaced by C to form $\hat{\rho}^{AC}$ and $\hat{\rho}^{BD}$ and where the product wavefunctions ab and cd are rearranged respectively into ac and bd . Since the product wavefunction b (or b') belongs solely to the fragment B (this would not be true for an eigenfunction), the wavefunctions, a , b , c , and d follow along with the fragments A, B, C, and D, with which they are associated. In other words, the quantum mechanics follows the chemistry; thus equation (27) becomes, after reorganization

$$\langle ab | \hat{\rho}^{AB}(\text{col}) | a'b' \rangle = \sum_{cd} \langle ac | \hat{\rho}^{AC} | a'c \rangle \langle bd | \hat{\rho}^{BD} | b'd \rangle \quad (28)$$

which gives $(\hat{E}\hat{\rho}^{\text{AB}})_{ab,a'b'}$ as

$$(\hat{E}\hat{\rho}^{\text{AB}})_{ab,a'b'} = \frac{1}{\tau_{\text{AB}}} \left[\sum_{cd} \hat{\rho}_{ac,a'c}^{\text{AC}} \hat{\rho}_{bd,b'd}^{\text{BD}} - \hat{\rho}_{ab,a'b'}^{\text{AB}} \right] \quad (29)$$

2 SHORT LIST OF COMMON EXCHANGE EVENTS

For a comprehensive list of exchange events, see Fraenkel.⁷ For a ‘hands-on’ description of how to obtain τ_e lineshape analysis, see Nageswara Rao.⁸

2.1 Mutual Exchange of Fragments

$$\hat{\rho}_{cd,c'd'}^{\text{CD}}(\text{col}) = \sum_{ab} \hat{\rho}_{ac,ac'}^{\text{AC}} \hat{\rho}_{bd,bd'}^{\text{BD}} \quad (31)$$

$$\hat{\rho}_{ac,a'c'}^{\text{AC}}(\text{col}) = \sum_{bd} \hat{\rho}_{ab,ab'}^{\text{AB}} \hat{\rho}_{cd,cd'}^{\text{CD}} \quad (32)$$

$$\hat{\rho}_{bd,b'd'}^{\text{BD}}(\text{col}) = \sum_{ac} \hat{\rho}_{ab,ab'}^{\text{AB}} \hat{\rho}_{cd,cd'}^{\text{CD}} \quad (33)$$

$$\hat{\rho}_{ab,a'b'}^{\text{AB}}(\text{col}) = \sum_{cd} \hat{\rho}_{ac,a'c'}^{\text{AC}} \hat{\rho}_{bd,b'd'}^{\text{BD}} \quad (34)$$

$$\hat{\rho}_{ab,a'b'}^{\text{AB}}(\text{col}) = \sum_c \hat{\rho}_{ac,a'c'}^{\text{AC}} \hat{\rho}_{b,b'}^{\text{B}} \quad (36)$$

$$\hat{\rho}_{c,c'}^{\text{C}}(\text{col}) = \sum_{ab} \hat{\rho}_{ac,a'c'}^{\text{AC}} \hat{\rho}_{b,b'}^{\text{B}} = \sum_a \hat{\rho}_{ac,ac'}^{\text{AC}} \quad (37)$$

$$\hat{\rho}_{ac,a'c'}^{\text{AC}}(\text{col}) = \sum_b \hat{\rho}_{ab,ab'}^{\text{AB}} \hat{\rho}_{c,c'}^{\text{C}} \quad (38)$$

$$\hat{\rho}_{b,b'}^{\text{B}}(\text{col}) = \sum_{ac} \hat{\rho}_{ab,ab'}^{\text{AB}} \hat{\rho}_{c,c}^{\text{C}} = \sum_a \hat{\rho}_{ab,ab'}^{\text{AB}} \quad (39)$$

2.2 Group Transfer

$$\hat{\rho}_{ab,a'b'}^{\text{AB}}(\text{col}) = \sum_{cd} \hat{\rho}_{abc,a'b'c}^{\text{ABC}} \hat{\rho}_{d,d}^{\text{D}} = \sum_c \hat{\rho}_{abc,a'b'c}^{\text{ABC}} \quad (41)$$

$$\hat{\rho}_{cd,c'd'}^{\text{CD}}(\text{col}) = \sum_{ab} \hat{\rho}_{abc,abc'}^{\text{ABC}} \hat{\rho}_{d,d'}^{\text{D}} \quad (42)$$

$$\hat{\rho}_{abc,a'b'c'}^{\text{ABC}}(\text{col}) = \sum_d \hat{\rho}_{ab,ab'}^{\text{AB}} \hat{\rho}_{cd,cd'}^{\text{CD}} \quad (43)$$

$$\hat{\rho}_{d,d'}^{\text{D}}(\text{col}) = \sum_{abc} \hat{\rho}_{ab,ab'}^{\text{AB}} \hat{\rho}_{cd,cd'}^{\text{CD}} = \sum_c \hat{\rho}_{cd,cd'}^{\text{CD}} \quad (44)$$

2.3 Dissociation–Recombination

$$\hat{\rho}_{ab,a'b'}^{\text{AB}}(\text{col}) = \hat{\rho}_{a,a'}^{\text{A}} \hat{\rho}_{b,b'}^{\text{B}} \quad (46)$$

$$\hat{\rho}_{a,a'}^{\text{A}}(\text{col}) = \sum_b \hat{\rho}_{ab,ab'}^{\text{AB}} \quad (47)$$

2.4 Unimolecular Rearrangements

These rearrangements include rotation, pseudorotation, and Berry rotation, where A is different from B:

$$\hat{\rho}_{a,a'}^{\text{A}}(\text{col}) = \hat{\rho}_{a,a'}^{\text{B}} \quad (49)$$

$$\hat{\rho}_{b,b'}^{\text{B}}(\text{col}) = \hat{\rho}_{a,a'}^{\text{A}} \quad (50)$$

2.5 Unimolecular Degenerate Rearrangements

This situation includes all rearrangements where the chemical identity of the species is preserved and the spins become scrambled. In this case the labels of spins are given by the order

$$\hat{\rho}_{abc,a'b'c'}^{\text{A}}(\text{col}) = \hat{\rho}_{acb,a'c'b'}^{\text{A}} \quad (52)$$

3 SYSTEMS UNDERGOING MORE THAN ONE EXCHANGE PROCESS

The exchange processes considered in the previous section all involved one step, and the exchange contributions to the density matrix equations had the form

$$\hat{E}\hat{\rho}^{\text{sp}} = (1/\tau_{\text{sp}})[\hat{\rho}^{\text{sp}}(\text{col}) - \hat{\rho}^{\text{sp}}] \quad (53)$$

Now, the question arises as to what is the form of $\hat{\rho}(\text{col})$ in a system undergoing several exchange processes at the same time.⁴ The result must clearly be the weighted average

$$\hat{\rho}^{\text{sp}}(\text{col}) = \sum_{\text{ex}} \frac{1/\tau_{\text{spex}}}{1/\tau_{\text{sp}}} \hat{\rho}(\text{col}_{\text{ex}}) \quad (54)$$

where ex sums over all exchange processes, τ_{sp} is the mean lifetime of species sp given as

$$\frac{1}{\tau_{\text{sp}}} = \sum_{\text{ex}} \frac{1}{\tau_{\text{spex}}} \quad (55)$$

and τ_{spex} is the survival time until sp undergoes a particular exchange step ex. Substituting equations (54) and (55) into equation (53) gives

$$\hat{E}\hat{\rho}^{\text{sp}} = \sum_{\text{ex}} (1/\tau_{\text{spex}})[\hat{\rho}^{\text{sp}}(\text{col}_{\text{ex}}) - \hat{\rho}^{\text{sp}}] \quad (56)$$

As an example, consider the following set of coupled exchange processes:

with

$$1/\tau_{\text{AB},a} = k_a \quad (60)$$

$$1/\tau_{\text{AB},b} = k_b(\text{C}) \quad (61)$$

$$1/\tau_{\text{AB},c} = k_c(\text{E}) \quad (62)$$

Then $\hat{E}\hat{\rho}^{\text{AB}}$ is given by

$$\begin{aligned} \hat{E}\hat{\rho}^{\text{AB}} = & k_a[\hat{\rho}^{\text{AB}}(\text{col}, a) - \hat{\rho}^{\text{AB}}] + k_b(\text{C})[\hat{\rho}^{\text{AB}}(\text{col}, b) - \hat{\rho}^{\text{AB}}] \\ & + k_c(\text{E})[\hat{\rho}^{\text{AB}}(\text{col}, c) - \hat{\rho}^{\text{AB}}] \end{aligned} \quad (63)$$

and the different $\hat{\rho}^{\text{AB}}(\text{col})$ terms can be readily obtained by use of the catalog in Section 2.

4 LINEARIZATION OF THE NONLINEAR EXCHANGE TERMS

As can be seen by looking at the examples in Section 2, $\hat{\rho}(\text{col})$ is often nonlinear. The nonlinear terms are made linear by noting that for low rf power:⁴

$$\hat{\rho}_A \simeq \hat{\rho}_0 + \hat{\rho}_1 \quad (64)$$

where

$$\hat{\rho}_0 = \frac{\exp(-\hat{\mathcal{H}}_A^0/kT)}{\text{Tr} \exp(-\hat{\mathcal{H}}_A^0/kT)} \simeq \frac{1 - \hat{\mathcal{H}}_A^0/kT}{(2I + 1)^{N_A}} \quad (65)$$

$\hat{\rho}_1$ is linear in the rf field, and N_A is the number of spins in molecule A. A typical off-diagonal matrix element at resonance (its greatest value) is given approximately as

$$\langle \alpha | \hat{\rho}_1 | \beta \rangle \simeq \frac{T_2 \omega_1 (\hbar \omega_0 / kT)}{(2I + 1)^{N_A}} \quad (66)$$

Thus the ratio of a diagonal to an off-diagonal matrix element is given approximately as

$$\frac{\rho_{\text{off-diagonal}}}{\rho_{\text{diagonal}}} \simeq T_2 \omega_1 (\hbar \omega_0 / kT) \quad (67)$$

which is very small for NMR operating conditions. Thus at low power one only need keep terms in $\hat{\rho}(\text{col})$ which are linear in the off-diagonal elements. For high power, where one expresses

$$\hat{\rho}_A \simeq \frac{1}{(2I + 1)^{N_A}} + \hat{\rho}_2 \quad (68)$$

a similar argument shows that one only need keep terms in $\hat{\rho}(\text{col})$ which are either linear in $\hat{\rho}_{2\text{off-diagonal}}$ or linear in $\hat{\rho}_{2\text{diagonal}}$.

Figure 1 Computer plot of an exchange coupled doublet for slow to fast exchange

5 DISCUSSION FOR A SIMPLE SPIN SYSTEM OF TECHNIQUES FOR OBTAINING THE EXCHANGE TIME τ_e

Figure 1 shows the one-dimensional (or CW) chemical exchange spectra for two exchanging protons. It illustrates the effects of exchange when τ_e varies from $1/\tau_e \ll \Delta\omega$ (see Figure 2), for which the doublet linewidth is approximately $1/T_2 + 1/\tau_e$, to the collapsed doublet, where for $1/\tau_e \gg \Delta\omega$ the linewidth is approximately $1/T_2 + \frac{1}{2}\Delta\omega^2\tau_e$.

5.1 Intermediate Exchange Rates

To obtain the exchange width in the intermediate range, i.e. for

$$\frac{1}{\tau_e} \gg \frac{1}{10} \frac{1}{T_2} \quad (69)$$

$$\Delta\omega^2\tau_e \gg \frac{1}{10} \frac{1}{T_2} \quad (70)$$

Figure 2 Schematic drawing of an exchange coupled doublet in the slow and fast exchange limits

one can use either CW lineshape or two-dimensional (2D) spectroscopy. We will first exhibit the CW lineshape for the doublet and then the two-dimensional mapping analog.

For the exchanging doublet AB where the doublet spins have the same $1/T_2$ and concentration and are separated by $2\Delta\omega$ (see Figure 2), the CW absorption lineshape is given as the real part of

$$M = \frac{2}{x^- - x^+} \left(\frac{x^- - 1/T_2}{x - x^+} - \frac{x^+ - 1/T_2}{x - x^-} \right) \quad (71)$$

where

$$x = i(\omega - \omega_0) \quad (72)$$

$$\omega_0 = \frac{1}{2}(\omega_{0A} + \omega_{0B}) \quad (73)$$

$$x^\pm = \left(\frac{1}{T_2} + \frac{1}{\tau_e} \right) \pm i \left[\Delta\omega^2 - \left(\frac{1}{\tau_e} \right)^2 \right]^{1/2} \quad (74)$$

For $1/\tau_e \ll \Delta\omega^2$, equation (71) is approximately given as

$$M \simeq \frac{1}{i(\omega - \omega_0 - \Delta) - 1/T_2 - 1/\tau_e} + \frac{1}{i(\omega - \omega_0 + \Delta) - 1/T_2 - 1/\tau_e} \quad (75)$$

with absorption at $\omega_0 \pm \Delta$ with widths $1/T_2 + 1/\tau_e$, and for $1/\tau_e \gg \Delta\omega$,

$$x^+ \simeq \left(\frac{1}{T_2} + \frac{1}{\tau_e} \right) - \left(\frac{1}{\tau_e} - \frac{1}{2}\Delta\omega^2\tau_e \right) \simeq \frac{1}{T_2} + \frac{1}{2}\Delta\omega^2\tau_e \quad (76)$$

$$x^- \simeq \left(\frac{1}{T_2} + \frac{1}{\tau_e} \right) + \left(\frac{1}{\tau_e} - \frac{1}{2}\Delta\omega^2\tau_e \right) \simeq \frac{2}{\tau_e} - \frac{1}{2}\Delta\omega^2\tau_e \quad (77)$$

$$M \simeq \frac{2}{2/\tau_e} \left[\frac{2/\tau_e}{i(\omega - \omega_0) - 1/T_2 - \frac{1}{2}\Delta\omega^2\tau_e} - \frac{\frac{1}{2}\Delta\omega^2\tau_e}{i(\omega - \omega_0) - 2/\tau_e} \right] \quad (78)$$

Thus, effectively, for $2/\tau_e \gg \frac{1}{2}\Delta\omega^2\tau_e$ there is only one line centered at $\omega = \omega_0$ with a width $(1/T_2) + (1/2)\Delta\omega^2\tau_e$.

The 2D description is described in detail by Ernst et al.⁹ One uses a series of three 90° pulses, as shown in Figure 3. (See *Two-Dimensional Methods of Monitoring Exchange*.)

The period t_m is a chemical exchange mixing time which exchange mixes the components from time period 1 which are precessing at the frequencies ω_A and ω_B . The result is a 2D spectrum as shown in Figure 4. The great advantage of 2D spectroscopy is that it explicitly exhibits the exchange pathways for the entire spectra.

5.2 Slow Exchange

To obtain $1/\tau_e$ when

$$\frac{1}{\tau_e} < \frac{1}{10} \frac{1}{T_2} \quad (79)$$

one can use selective inversion, selective saturation, or amplitude modulated saturation.¹⁰ The problem is most simply illustrated by using selective inversion. For the equal concentration two spin exchange coupled system the diagonal components can be expressed as the coupled Bloch equations:

$$\dot{M}_{ZA} = -\frac{1}{T_1}(M_{ZA} - M_{0A}) - \frac{1}{\tau_e}(M_{ZA} - M_{ZB}) \quad (80)$$

$$\dot{M}_{ZB} = -\frac{1}{T_1}(M_{ZB} - M_{0B}) - \frac{1}{\tau_e}(M_{ZB} - M_{ZA}) \quad (81)$$

Now, if $1/\tau_e < 1/T_1$ the effect of the $(1/\tau_e)(M_{ZA} - M_{ZB})$ term will be very small since $M_{ZA} \approx M_{ZB}$, but if we invert M_{ZB} , the exchange term in equation (81) will, in effect, be

$$-\frac{1}{\tau_e}(M_{ZA} + M_{ZB}) \quad (82)$$

Figure 3 Two-dimensional spectra of fast and slow exchange. (Reproduced by permission of Clarendon Press from R. Ernst, G. Bodenhausen, and A. Wokaum, *Principles of Nuclear Magnetic Resonance in One and Two Dimensions*, Clarendon Press, Oxford, 1987, Chap. 9)

Figure 4 Two-dimensional exchange spectra showing the exchange of the two methyl groups in *N,N*-dimethylacetamide for five different temperatures, demonstrating the lineshape effects for rapid chemical exchange

which will amplify the exchange process. The solution for $M_{ZA}(t)$ after the inversion of M_{ZB} at $t = 0$ is given as

$$M_{ZA}(t) = M_0 \left\{ 1 + \exp \left[- \left(\frac{1}{T_1} + \frac{2}{\tau_e} \right) t \right] - \exp \left(- \frac{t}{T_1} \right) \right\} \quad (83)$$

which is plotted in Figure 5 for

$$\tau_e = 10T_1 \simeq 100T_2 \quad (84)$$

We can further enhance the observed depolarization of M_{ZA} by again inverting M_{ZB} at $t = 2T_1$ to obtain the result given in Figure 6.

The various exchange pathways can be explored by selectively inverting spins. This can be done in one fell swoop using 2D spectroscopy, but slow exchange processes will be missed.¹⁰

We finally suggest an alternative procedure to obtain slow exchange. We saturate the B spin using an amplitude-modulated saturation. Again consider the exchange coupled

Figure 5 Plot of $M_{ZA}(t)$ as a function of time as given in equation (83) for M_{ZB} inverted at $t = 0$

Figure 6 Plot of $M_{ZA}(t)$ as a function of time after M_{ZB} was inverted at $t = 0$ and $t = 2T_1$

Bloch equations, but now with a saturating rf field acting on the B sites:

$$\dot{M}_{ZA} = -\frac{1}{T_1}(M_{ZA} - M_{0A}) - \frac{1}{\tau_e}(M_{ZA} - M_{ZB}) \quad (85)$$

$$\dot{M}_{ZB} = -\frac{1}{T_1}(M_{ZB} - M_{0B}) - \frac{1}{\tau_e}(M_{ZB} - M_{ZA}) + \omega_1^2 T_2 M_{ZB} \quad (86)$$

Note that for $1/\tau_e = 0$, we obtain the standard saturated value for M_{ZB} :

$$M_{ZB} = \frac{M_{0B}}{1 + T_1 T_2 \omega_1^2} \quad (87)$$

We now choose the time-dependent rf field so that

$$\omega_1^2 = \omega_{10}^2(1 + \cos \alpha t) \quad (88)$$

The coupled equations are solved by writing

$$M_{ZA}(t) = M_{A0} + \sum_i M_{Aic} \cos(n_i \alpha t) + \sum_i M_{Ais} \sin(n_i \alpha t) \quad (89)$$

$$M_{ZB}(t) = M_{B0} + \sum_i M_{Bic} \cos(n_i \alpha t) + \sum_i M_{Bis} \sin(n_i \alpha t)$$

Figure 7 Plot of $M_{Aic}(t)$ as a function of α [see equation (89)]

If $\alpha < 1/\tau_e$, we expect the magnetization on the A site to follow the modulation, but if $\alpha > 1/\tau_e$, we expect the modulation to be too fast to follow and thus the response on the A site to be reduced. This intuitive argument is borne out by plotting M_{Aic} as a function of α (Figure 7). What is important in this procedure is that one can introduce an artificial time variation to obtain selectively very long τ_e values. Modification of this procedure may make it better suited for experimentally determining τ_e .

5.3 Fast Exchange

To obtain information on τ_e when

$$\frac{\Delta\omega^2 \tau_e}{2} \ll \frac{1}{T_2} \quad (90a)$$

we can look at the FID version of equation (71), which is

$$\begin{aligned} \text{FID}(t) \sim \exp \left[- \left(\frac{1}{T_2} + \frac{1}{2} \Delta\omega^2 \tau_e \right) t \right] \\ - \frac{1}{4} \Delta\omega^2 \tau_e^2 \exp \left(- \frac{2t}{\tau_e} \right) \end{aligned} \quad (90b)$$

If we could digitize $\text{FID}(t)$ for times much less than τ_e , we could plot $(d/dt)[\text{FID}(t)]$ and $(d^2/dt^2)[\text{FID}(t)]$. This is easy for a nonexperimentalist to say. The second derivative is then given as

$$\begin{aligned} \frac{d^2}{dt^2} \text{FID}(t) = \left(\frac{1}{T_2} + \frac{1}{2} \Delta\omega^2 \tau_e \right)^2 \exp \left[- \left(\frac{1}{T_2} + \frac{1}{2} \Delta\omega^2 \tau_e \right) t \right] \\ - \left(\frac{2}{\tau_e} \right)^2 \frac{1}{4} \Delta\omega^2 \tau_e^2 \exp \left(- \frac{2t}{\tau_e} \right) \end{aligned} \quad (91)$$

$$\frac{d^2}{dt^2} \text{FID}(t) \simeq \frac{1}{T_2^2} \exp \left(- \frac{t}{T_2} \right) - \Delta\omega^2 \exp \left(- \frac{2t}{\tau_e} \right) \quad (92)$$

where now the fast decaying exponential has the largest amplitude.

6 THE EXCEPTION WHEN THE EXCHANGE TIME τ_e IS EQUAL TO OR LESS THAN THE CORRELATION TIME τ_c

The circumstance under which the exchange time τ_e approaches or is less than the correlation time τ_c could arise when a small molecule hops on and off a very large molecule. The large molecule could have a rotational correlation time longer than the hopping time τ_e .

This problem has been treated by a number of authors¹¹ with various degrees of approximation. In the standard approach ($\tau_c \ll \tau_e$) one obtains a time-independent relaxation operator $\hat{R}_A$. If the time for the exchange interaction approaches that of the relaxation interaction, the expression²

$$\hat{R}_A \hat{\rho}_A \simeq \int_{-\infty}^{+\infty} \dots d\tau \quad (93)$$

is no longer valid and must be replaced by

$$\hat{R}_A \hat{\rho}_A \approx \int_{-t}^{+t} \dots d\tau \quad (94)$$

where t is the elapsed time after the last exchange collision. This line of reasoning leads to the result that the collapsed linewidth is given by

$$\frac{1}{T_2} + \frac{1}{2} \tau_e \Delta\omega^2 - \frac{1}{T_2} \frac{\tau_c}{\tau_e}, \text{ valid for } \frac{\tau_c}{\tau_e} < 1 \quad (95)$$

A more rigorous approach¹² starts with

$$\begin{aligned} \dot{\hat{\rho}}_A = & -i[\hat{\mathcal{H}}_Z^A + \hat{\mathcal{H}}_{\text{dipolar}}^A, \hat{\rho}_A] - i[\hat{\mathcal{H}}_{\text{rf}}^A, \hat{\rho}_A] \\ & + D_A \nabla_A^2 \hat{\rho}_A - \hat{E}_{AB} \hat{\rho}_A \end{aligned} \quad (96)$$

treating relaxation and exchange simultaneously. The result for $\Delta\omega \approx 0$ is that the linewidth is given (for equal spin concentration) as

$$\frac{1}{T_2} - \frac{1}{T_2} \left(\frac{\tau_c/\tau_e}{1 + \tau_c/\tau_e} \right) \quad (97)$$

which agrees with equation (95) in the limit $\tau_c/\tau_e < 1$.

7 THE EXCEPTION WHEN THE EXCHANGE RELAXATION IS NOT EXPONENTIAL

For nonexponential exchange,^{13,14} we replace equation (14) with

$$\dot{\hat{\rho}}^{\text{AB}} = \int_{-\infty}^{+t} dt' \exp[-(\hat{\mathcal{L}}_S^{\text{AB}} + \hat{\mathcal{L}}_R^{\text{AB}})] \psi(t-t') \hat{\rho}_{\text{col}}^{\text{AB}}(\text{col}, t') dt' \quad (98)$$

where for exponential relaxation¹²

$$\begin{aligned} \psi_{\text{exp}}(t) dt &= \lim \left[\exp\left(-\frac{t}{\tau_e}\right) - \exp\left(-i\frac{(t+dt)}{\tau_e}\right) \right] \\ &= \exp\left(-\frac{t}{\tau_e}\right) \frac{dt}{\tau_e} \end{aligned} \quad (99)$$

For nonexponential relaxation,

$$\psi_{\text{non-exp}}^{(t)}(t) dt = \lim [\phi(t) - \phi(t+dt)] \quad (100)$$

If we represent

$$\phi(t) = \sum_j p_j \exp\left(-\frac{t}{\tau_j}\right) \quad (101)$$

then equation (99) becomes

$$\psi(t) dt = \sum_i \tau_j^{-1} p_j \exp\left(-\frac{t}{\tau_j}\right) dt \quad (102)$$

It follows that equation (98) modified for the nonexponential autocorrelation function becomes

$$\begin{aligned} \hat{\rho}^{\text{A}}(t) &= \int_{-\infty}^t dt' \exp[(\hat{L}_A + \hat{R}_A)(t-t')] \\ &\times \sum_j \tau_j^{-1} p_j \exp\left(-\frac{t-t'}{\tau_j}\right) \hat{\rho}_{\text{col}}^{\text{A}}(t') \end{aligned} \quad (103)$$

To express equation (103) in differentiated form, write

$$\hat{\rho}^{\text{AB}}(t) = \sum_j p_j \hat{\rho}_j^{\text{AB}}(t) \quad (104)$$

Substituting equation (104) in equation (103), one obtains the coupled equations for the j th component as

$$\begin{aligned} \hat{\rho}_j^{\text{AB}}(t) &= \int_{-\infty}^t dt' \exp[(\hat{L}_A + \hat{R}_A)(t-t')] \tau_j^{-1} \\ &\times \exp\left(-\frac{t-t'}{\tau_j}\right) \hat{\rho}_{\text{col}}^{\text{A}}(t') \end{aligned} \quad (105)$$

which, upon differentiation with respect to t , becomes

$$\dot{\hat{\rho}}_{Aj}(t) = -i[\hat{\mathcal{H}}_A, \hat{\rho}_{Aj}] + \hat{R}_A \hat{\rho}_{Aj} - \tau_j^{-1} (\hat{\rho}_{Aj} - \hat{\rho}_{\text{col}}) \quad (106)$$

To proceed further, we must choose a form for $\phi(t)$. A suggested form is the so-called stretched exponential:¹⁵

$$\exp[-(t/\tau_p)^\alpha] \quad (107)$$

The solution for the stretched exponential for $\alpha = 1$ and for $\alpha = 0.3$ is given in Kaplan and Garraway¹³ and is

Figure 8 Chemical exchange lineshapes simulated for a distribution of correlation times described by the stretched exponential autocorrelation function $\exp[-(t/\tau_p)^\alpha]$. The situation corresponds to two-site exchange with equal populations and relaxation time $2\Delta\omega\tau_{2A} = 40$, $2\Delta\omega\tau_{2B} = 20$. Spectra are shown at decade intervals of τ_p . The $\alpha = 1$ limit recovers the single correlation time model. (Reproduced by permission from J. I. Kaplan and A. N. Garroway, *J. Magn. Reson.*, 1985, **64**, 32)

shown in Figure 8 for $2\Delta\omega\tau_{2A} = 40$ and $2\Delta\omega\tau_{2B} = 20$ as a function of $\log(2\Delta\omega\tau_p)$. As can be seen, the line-shape between the fast and slow exchange rates is sensitive to α .

The origin of nonexponential relaxation arises from memory, i.e. the upcoming exchange event is functionally related to the preceding exchange event. A simple model for this is given in Kaplan.¹⁴ The exchange event is a transformation of a molecule from one geometrical structure (I_{ABB}) to another (II_{BBA}). The transformation can only proceed when the molecule is in a normal mode whose motion mimics the motion necessary to make the geometrical rearrangement. The modes which make the rearrangement possible are called 'hopping modes' and all other modes are called 'nonhopping modes'.

The normal mode coupling of configurations I and II can be written in matrix form as

$$\begin{bmatrix} -\frac{1}{\tau_{h,nh}} - \frac{1}{\tau_h} & \frac{1}{\tau_{nh,h}} & & \frac{1}{\tau_h} \\ \frac{1}{\tau_{h,nh}} & & -\frac{1}{\tau_{nh,h}} & \\ & -\frac{1}{\tau_{nh,h}} & \frac{1}{\tau_{h,nh}} & \\ \frac{1}{\tau_h} & & \frac{1}{\tau_{nh,h}} & -\frac{1}{\tau_{h,nh}} - \frac{1}{\tau_h} \end{bmatrix} \begin{bmatrix} N_{hI} \\ N_{nhI} \\ N_{nhII} \\ N_{hII} \end{bmatrix} = \begin{bmatrix} \dot{N}_{hI} \\ \dot{N}_{nhI} \\ \dot{N}_{nhII} \\ \dot{N}_{hII} \end{bmatrix} \quad (108)$$

where N_h (N_{nh}) is the population of the hopping (nonhopping) modes, τ_h defines the hopping–hopping time, and $\tau_{h,nh}$ defines the hopping–nonhopping time within configuration I

Figure 9 Plot of equation (106) with $\Delta\omega = 10$; $1/T_2 = 1$; $N_{nh}/N_h = 2$; $1/T_{h,nh} = 4$; $1/T_{nh,h} = 2$; and (a) $1/T_h = 2$, (b) $1/T_h = 6$, (c) $1/T_h = 10$. (Reproduced by permission from J. I. Kaplan, *J. Magn. Reson.*, 1991, **91**, 39)

or II. $\tau_{h,nh}$ and $\tau_{nh,h}$ are related as

$$\frac{\tau_{h,nh}}{\tau_{nh,h}} = \frac{N_{hequil.}}{N_{nhequil.}} \quad (109)$$

The application of this model to NMR chemical exchange is expressed by the following density matrix equation:

$$\begin{bmatrix}
-\left(\frac{1}{T_2} + \frac{1}{\tau_h} + \frac{1}{\tau_{h,nh}}\right) & \frac{1}{\tau_{nh,h}} & \frac{1}{\tau_h} \\
\frac{1}{\tau_{nh,h}} & -\left(\frac{1}{T_2} + \frac{1}{\tau_{nh,h}}\right) & \frac{1}{\tau_h} \\
\frac{1}{\tau_h} & \frac{1}{\tau_{nh,h}} & -\left(\frac{1}{T_2} + \frac{1}{\tau_{nh,h}}\right)
\end{bmatrix}
\begin{bmatrix}
\rho_{I_h} \\
\rho_{I_{nh}} \\
\rho_{II_{nh}}
\end{bmatrix}
=
\begin{bmatrix}
C \\
C \\
C
\end{bmatrix}
\quad (110)$$

Lineshapes arising from equation (110) are shown in Figure 9.

1 INTRODUCTION

Chemical exchange, i.e. the transfer of atoms, molecules or molecular groups between two or more different environments or regions, is a phenomenon encountered frequently in studies by NMR of a wide variety of chemical, physical and biological systems. Different environments are usually revealed in NMR experiments through distinct resonance frequencies, spin–spin coupling constants, or relaxation times characteristic of the regions between which chemical exchange takes place. The types of atomic or molecular motion most often investigated on metal surfaces include surface diffusion, adsorption and desorption, exchange between different surface sites or different types of adsorbed species, molecular reorientation, and reorientation of molecular groups.

Because NMR requires at least ca. 10^{18} spins at the surface to be able to detect a signal, single crystal surfaces cannot be studied (10^{15} spins). However, introducing the metal in the form of small particles with diameters in the order of nanometers into porous materials, provides a sufficiently high number of surface sites for adsorption to be studied by NMR. These support materials are mostly oxide compounds like silica, alumina, titania, or zeolites with high internal surfaces of several hundred square meters. At the same time, highly dispersed supported metals, e.g. group VIII elements like ruthenium, rhodium, palladium, osmium, iridium, and platinum, are very often of interest in basic and applied research in catalysis (see also *Supported Metal Catalysts*, and *Adsorbed Species: Spectroscopy and Dynamics*).

Several NMR techniques are available to study exchange phenomena of adsorbed species. Spin–lattice relaxation¹ measurements are useful if chemical exchange dominates as a source for relaxation, or can be separated from other relaxation mechanisms, e.g. relaxation via the conduction electrons of the metal, called Korringa relaxation (see *Electron–Nuclear Hyperfine Interactions*). To be investigated by relaxation measurements, the characteristic time constants of exchange τ_{ex} have to be in the order of 10^{-9} s for spin–lattice relaxation in the laboratory frame to 10^{-5} s for spin–lattice relaxation in the rotating frame.¹ For a review of the relaxation method used to study the dynamics on surfaces we refer the reader to the literature.^{2–4} The analysis of lineshapes or resonance shifts

obtained by conventional NMR techniques are sensitive in the dynamic range of $10^{-6} \leq \tau_{\text{ex}} \leq 10^{-3}$ s. Spin labeling methods extend this range up to more than 10^{-1} s. Two-dimensional NMR techniques, applicable in approximately the same slow dynamic range, are most effective if the exchanging species exhibit separate NMR peaks or if well-defined lineshapes due to anisotropic interactions can be observed.⁵

In the present article the theoretical basis necessary to understand the evolution of nuclear spin magnetization influenced by chemical exchange is outlined briefly. The reader is introduced to spin-labeling and two-dimensional (2D) NMR techniques, which are frequently used to monitor exchange. Finally, experimental examples regarding chemical exchange on metal surfaces are discussed.

2 THEORY OF MAGNETIZATION EXCHANGE

In the following it is assumed that the spatial motion of molecules or atoms can be described classically. If all spin interactions are secular with respect to the Zeeman interaction, i.e., the corresponding interaction Hamiltonians commute with the Zeeman Hamiltonian, then each spin can be considered as being subjected to a local field arising from the environment, superimposed on the external static field. Chemical exchange has the effect of causing random fluctuations of the local field. For example, a nuclear spin situated in a molecule or atom, which jumps randomly between two regions on a surface, such that each region gives rise to a different isotropic resonance shift, experiences a random modulation of its resonance frequency. The influence of such frequency fluctuations upon the NMR lineshape was first treated by Hahn, Maxwell, Gutowsky, McCall, and Slichter.⁶

If the spin Hamiltonian contains nonsecular terms, arising, for example, from J couplings observed commonly in liquids, a quantum-mechanical treatment (spin density matrix formalism) is required.⁷ Splittings due to J couplings are often difficult to detect in NMR studies of adsorbates on metal surfaces because of insufficient spectral resolution, caused by the heterogeneity of the system, leading to distributions of isotropic chemical or Knight shifts, and/or the presence of ‘solid-like’ spin interactions much stronger than J coupling, like chemical shift anisotropy (see *Internal Spin Interactions and Rotations in Solids*) and paramagnetic shifts.

We confine ourselves here exclusively to the case of secular spin interactions, leading to a classical probabilistic model for the magnetization exchange originating from chemical exchange processes. The probabilistic model is commonly represented by a stationary Markov process,^{8,9} allowing the derivation of equations of motion for the nuclear spin magnetization in the form of generalized Bloch equations.^{9–11} The evolution of longitudinal and transversal magnetization components for all regions, between which exchange takes place, are given as a system of coupled differential equations with rate coefficients describing the magnetization exchange process. Solving these equations is a standard problem of analysis and matrix algebra (see Ernst et al.¹¹ and Jeener et al.¹³) and enables explicit calculation of NMR lineshapes.

Figure 1 illustrates the principal effects on the NMR lineshapes originating from magnetization exchange between two regions or sites. Regions A and B, populated by N_A and N_B spins, respectively, are characterized by distinct resonance

Figure 1 (a) NMR lineshape versus $\delta\omega\tau_{\text{ex}}$ for symmetric two-site exchange ($N_A = N_B$). (b) Variation of the resonance frequency in the fast exchange limit as a function of $N_A:N_B$

frequencies ω_A and ω_B , $\delta\omega = \omega_B - \omega_A$. This difference of resonance frequencies may be caused by different isotropic chemical or Knight shifts. In the slow exchange limit, $\delta\omega\tau_{\text{ex}} \gg 1$, where τ_{ex} is a characteristic time constant for the exchange process, two separate lines appear in the NMR spectrum [Figure 1(a)], which become broadened with decreasing $\delta\omega\tau_{\text{ex}}$, and coalesce to a single broad line at $\delta\omega\tau_{\text{ex}} \approx 1$. With $\delta\omega\tau_{\text{ex}}$ decreasing further, only one single ‘exchange-averaged’ narrow line is observed (fast exchange limit, $\delta\omega\tau_{\text{ex}} \ll 1$). The spectra in Figure 1(b) were calculated for the fast exchange limit varying the ratio $N_A:N_B$ of spin numbers in regions A and B, leading to a variation in the resonance frequency of the exchange averaged resonance line as well as to a broadening for values of $N_A:N_B$ near unity. The dependence of the resonance shift δ on N_A and N_B can be expressed for the fast exchange limit as the weighted average:

$$\delta = \frac{N_A}{N_A + N_B} \delta_A + \frac{N_B}{N_A + N_B} \delta_B \quad (1)$$

of the individual resonance shifts δ_A and δ_B . The mathematical formalism to calculate the above lineshapes is still applicable if anisotropic interactions, to be described by interaction tensors, e.g. chemical shift anisotropy, are present. However, because of the random spatial orientations of the principal tensor axes in a powder sample, the resulting orientation dependence of the resonance frequencies has to be taken into account to obtain the lineshape.¹⁰

3 ADVANCED NMR TECHNIQUES TO MONITOR EXCHANGE

As shown above, no significant changes of the one-dimensional NMR lineshapes or frequencies occur in the slow exchange limit. More advanced NMR techniques are available to detect such slow exchange processes.

3.1 Spin Labeling by Selective Excitation

The idea of spin labeling is based on the fact that the actual chemical exchange process, being in thermal equilibrium, causes an exchange of spin magnetization.¹² The latter is initially prepared by irradiation of rf pulses to be in nonequilibrium. The irradiation of an rf pulse, or a sequence of rf pulses affects only spins resonating within the spectral excitation window defined by the Fourier transform of the pulse sequence [Figure 2(a) and (b)]. Although this Fourier picture is only an approximation when selective saturation or inversion is considered,¹² it is a useful qualitative description. Denoting the length of a single rf pulse or the total duration of a pulse sequence by τ_p , the excitation width in the frequency domain is proportional to $1/\tau_p$, with the rf carrier frequency in the center of the excitation window. The irradiation of either a long pulse of low rf power or a sequence of strong, but very short pulses, as indicated in Figure 2(a), allows selective excitation of spins. The pulse sequence can be adjusted to act in total like a 90° pulse (selective saturation) or a 180° pulse [selective inversion, illustrated in Figure 2(c)]. Therefore, spins within the spectral window can be labeled, for example, by inversion of their magnetization, while spins which resonate outside the window remain unaffected. If a pulse sequence is used, excitation sidebands also occur [Figure 2(b)]. During a subsequent time interval τ_m [Figure 2(a)] the spin system is allowed to undergo free time evolution. The NMR signal is detected finally by a short (nonselective) 90° pulse. Selective excitation (saturation or inversion) of a narrow frequency band within a broad NMR line, for example, caused by chemical shift anisotropy, is called ‘spectral hole-burning’. If chemical exchange is present, the labeled spins may change their resonance frequencies resulting in a redistribution of spin

Figure 2 Spin labeling by selective excitation: (a) pulse sequence, (b) Fourier transformation of the train of equidistant pulses, and (c) NMR spectrum showing a selectively inverted line

magnetization toward spectral regions outside of the selected window. The recovery of the spectral hole, or of the intensity of an inverted single resonance line, can be measured as a function of the recovery time τ_m to reveal the kinetics of a chemical exchange process.

Magnetization recovery is also caused by spin–lattice relaxation of the spin magnetization. Only exchange processes with a characteristic time τ_{ex} shorter than the spin–lattice relaxation time T_1 can be observed. Spin-labeling becomes ineffective if the chemical exchange process is faster than the spin-labeling process itself (characteristic time constant τ_p). Thus accessible by spin-labeling techniques are exchange processes within a timescale $\tau_p < \tau_{ex} < T_1$.

3.2 Two-Dimensional Exchange NMR

Two-dimensional exchange NMR techniques¹³ are based on the idea of measuring the frequency of spin magnetization components at two different times during the NMR experiment. After the initial preparation period, which consists of a waiting period to allow equilibration of the longitudinal magnetization and irradiating the first $\pi/2$ pulse, transversal magnetizations are present, oscillating with frequencies ω_A and ω_B during the time t_1 [evolution period, Figure 3(a)] corresponding to spins located in regions A and B. A second $\pi/2$ pulse converts the magnetization present at time t_1 into longitudinal magnetization. During the mixing time τ_m (usually much longer than the time t_1) slow chemical exchange leads to a random modulation of the precession frequencies of the two magnetization components M_{zA} and M_{zB} . Spins which were resonating at ω_A at the end of the period t_1 may resonate at either ω_A or ω_B at the end of the mixing period τ_m (and vice versa). The NMR signal is detected after the final $\pi/2$ pulse during the time period t_2 . Repeating the experiment by incrementing the time t_1 in small steps, yields a two-dimensional time-domain interferogram which after 2D Fourier transformation¹¹ with respect to t_1 and t_2 gives the 2D NMR spectrum $S(\omega_1, \omega_2)$. If exchange occurs between A and B, cross peaks are observed, labeled A $\rightarrow$ B and B $\rightarrow$ A in Figure 3(b), in addition to main peaks A and B located along the principal diagonal.¹⁴

4 CHEMICAL EXCHANGE OF ADSORBED SPECIES ON METAL SURFACES: EXAMPLES

Chemical exchange phenomena at or near metal surfaces observed by NMR encompass a wide dynamical range extending from the fast exchange limit ($\tau_{ex} < 10^{-5}$ s) to extremely slow processes ($\tau_{ex} > 1$ s). The details of the chemical exchange processes might be quite different, originating, for example, from adsorption or desorption, exchange between different surface sites, exchange between different populations of adsorbed species or surface diffusion.¹⁵

4.1 Exchange Dynamics of CO Adsorbed on Metals

Carbon-13 spin labeling techniques have been applied by Duncan, et al.¹⁶ to elucidate in detail surface diffusion of

Figure 3 (a) Basic 2D NMR pulse sequence to monitor exchange. (b) Schematic representation of a 2D NMR spectrum for exchange between two sites A and B

CO and slow exchange between different carbonyl species adsorbed on rhodium. Molitor and Apple¹⁷ performed ^{13}C NMR powder lineshape calculations for reorientating dicarbonyl groups bonded to rhodium. Surface diffusion of CO chemisorbed on palladium has been investigated by means of ^{13}C relaxation measurements and lineshape analysis.¹⁸

4.2 Fast Exchange of Hydrogen on Metal Surfaces

Proton NMR peaks of hydrogen interacting with metal surfaces are commonly shifted to lower frequency (i.e. upfield) due to the Knight shift interaction and reveal relatively small linewidths, especially at elevated external H_2 pressures and temperatures above room temperature, indicating high intrinsic mobility. Variations of the resonance frequency of ^1H NMR peaks, attributed to hydrogen on the metal surface, versus pressure (i.e. changing the number of hydrogen atoms or molecules on the surface) may be caused by at least two different mechanisms: (i) fast exchange between surface environments with different Knight shifts [as illustrated in Figure 1(b)]; and (ii) by a variation of the Knight shift interaction itself, because the latter may be a function of the surface coverage. As pointed out above, fast exchange between two regions leads to an averaged NMR line representing hydrogen in both regions. Variation of the resonance shift

Figure 4 ^1H NMR resonance shift δ for hydrogen adsorbed on ruthenium–copper bimetallic particles and fraction X_{Ru} of surface ruthenium as a function of the copper content

with pressure, or coverage, has been observed quite frequently by ^1H NMR¹⁹ or ^2H NMR²⁰ for hydrogen adsorbed on various metals like platinum, rhodium, and ruthenium (see also refs. 18–20 and 23–24 given in Wu et al.¹⁹). The resonance shift variation of hydrogen due to fast exchange between different surfaced regions has been used to monitor the surface composition of bimetallic particles.²¹ In this case hydrogen atoms are rapidly exchanging between sites on the bimetallic particle surface, composed of sites with different Knight shifts for adsorbed hydrogen. As shown in Figure 4, on particles consisting of pure ruthenium, hydrogen resonates at -62 ppm [to low frequency relative to tetramethylsilane (TMS)]. Increasing the total copper content of the sample leads to a systematic decrease of the ^1H NMR resonance shift δ , approaching asymptotically the value of -49 ppm for a copper content near 80 at%. This shift value is regarded as the resonance shift for hydrogen adsorbed on copper sites of ruthenium–copper bimetallic particles. Applying equation (1) inserting $\delta_{\text{Cu}} = -49$ ppm and $\delta_{\text{Ru}} = -62$ ppm, the fraction $X_{\text{Ru}} = N_{\text{Ru}}/(N_{\text{Ru}} + N_{\text{Cu}})$ of ruthenium atoms exposed at the particle surface can be determined (see Figure 4). Therefore, in this example the ^1H NMR resonance shift provides a sensitive measure for the composition of the surface.

4.3 Slow Exchange Between Different Hydrogen Populations on the Metal Surface

Figure 5(a) shows an in situ ^1H NMR spectrum of silica supported ruthenium, obtained at $T = 400$ K and at an external H_2 pressure of 300 Torr.²² Two distinct resonance lines (denoted as α and β) are observed, originating from two different hydrogen species, characterized by different heats of adsorption. The 2D exchange NMR spectrum [Figure 5(b)] was obtained by the pulse sequence illustrated in Figure 3(a). The cross peaks reveal a slow exchange process within the timescale of the experiment, given by the mixing time $\tau_{\text{mix}} = 2$ ms, occurring between α and β hydrogen, but there is no exchange within this timescale between the α or β species and the hydrogen residing on the silica support. Spin

Figure 5 (a) Conventional ^1H NMR spectrum of silica supported ruthenium. (b) 2D exchange NMR spectrum at $T = 400$ K and external H_2 pressure $p = 300$ Torr

labeling of one of the two spin species, α or β , by selective excitation (Figure 2) allows the determination of the average time constant, $\tau_{\text{ex}} = 700 \mu\text{s}$, for the magnetization exchange between α and β hydrogen.

1 INTRODUCTION

The effect of dynamic processes on high-resolution NMR spectra in liquids was first observed¹ in 1953 soon after the discovery of the chemical shift² and spin–spin coupling phenomena.^{1,3} Since then the effect has been extensively used to study a wide range of dynamic processes in liquids including protolysis, solvation, hindered rotation, bond shift tautomerism, and a variety of other isomerization reactions.^{4,5} The effect of dynamic processes on the high-resolution spectra is manifested in line broadening, coalescence, and eventual line narrowing, yielding motionally averaged spectra with average magnetic parameters. The effect on the lineshape is most pronounced when the exchange rate is of the order of the magnetic interactions. For protons these range from several hertz to several kilohertz, while for ¹³C the range is an order of magnitude larger. Quantitative studies can generally be made within the range where the lifetime broadening or the exchange-narrowed linewidth exceeds that of the natural width, i.e. $1\text{--}10^6\text{ s}^{-1}$ for protons and one to two orders of magnitude faster for carbon-13.

Proton or carbon-13 high-resolution spectra of molecules dissolved in liquid crystalline solvents usually exhibit more complicated structures than in normal (isotropic) liquids and often span a wider frequency range.⁶ This is so because in anisotropic solvents, in addition to the scalar spin–spin coupling and isotropic chemical shift, anisotropic interactions also affect the spectrum. These include intramolecular dipole–dipole interactions, anisotropic indirect spin–spin couplings, anisotropic chemical shifts, and, for $I > \frac{1}{2}$ nuclei, also quadrupolar interactions. The fast anisotropic motion of the molecules reduces these interactions, but unlike in isotropic liquids their averages are, in general, not zero and depend on the ordering characteristics of the molecules in the liquid crystals. If the number of magnetic nuclei in the molecule is not too large (say below 10) a well-resolved high-resolution spectrum

can usually be observed, but for more nuclei the number of lines becomes exceedingly large and the spectrum unresolved. It should be emphasized that the fast translational diffusion completely averages out the intermolecular dipolar interactions. Otherwise a featureless spectrum as in solids would always be observed.

When the solute molecules dissolved in liquid crystals undergo dynamic processes, lineshape changes similar to those observed in isotropic liquids take place.⁷ We refer to this phenomenon as ‘dynamic NMR in liquid crystalline solvents’ and in the present article we outline its basic theory and review some applications. Because of the more complex structure of the spectra in liquid crystalline solutions the interpretation is more complicated, but the basic principles are the same as in isotropic liquids. On the other hand, due to the larger interactions involved, the dynamic range over which kinetic parameters can be measured is much wider. Nuclei with spins $I > \frac{1}{2}$ usually exhibit splittings due to quadrupole interactions which are often much larger than the dipolar or chemical shift interactions. The structure of the spectrum is then predominantly determined by the quadrupole splittings with the other interactions often within the experimental linewidth.

We start the review by extending the theory of dynamic lineshape in isotropic liquids to the liquid crystalline case by adding anisotropic terms to the spin Hamiltonian (Section 2). After a short section (3) dealing with some experimental aspects, we review applications (Section 4) for spin $I = \frac{1}{2}$ nuclei (¹H and ¹³C), including the use of multiple quantum spectroscopy (Section 5). In Sections 6 and 7 we discuss applications of one- and two-dimensional dynamic NMR to deuterium and in Section 8 we briefly describe a dynamic deuterium study using quadrupole echo pulse trains.

2 DYNAMIC NMR LINESHAPES IN LIQUID CRYSTALLINE SOLUTIONS

The theory of dynamic NMR lineshapes in anisotropic liquids is, in principle, identical to that for isotropic liquids.^{1,5,8–12} However, since dipolar interactions involve essentially all magnetic nuclei in the molecule, and for homonuclei cases these interactions are usually larger than the chemical shifts, the NMR spectra always correspond to combination transitions. The simple Bloch–McConnell type treatment⁸ is therefore not adequate for the analysis of the dynamic lineshapes and the more general density matrix formalism must be used.^{9–13} We shall restrict ourselves to intramolecular rearrangement kinetics because higher order processes involving two or more molecules¹⁰ have not been applied so far in liquid crystalline solutions. The equation of motion of the density matrix, $\hat{\rho}(t)$, during free induction decay, is then:

$$\begin{aligned} \frac{d\hat{\rho}(t)}{dt} = & -i[\hat{\mathcal{H}}, \hat{\rho}(t)] + k[\hat{R}\hat{\rho}(t)\hat{R}^{-1} - \hat{\rho}(t)] - \hat{\rho}_{\text{od}}(t)/T_2 \\ & - [\hat{\rho}_0 - \hat{\rho}_{\text{dg}}(t)]/T_1 \end{aligned} \quad (1)$$

where $\hat{R}$ is an operator describing the exchange process, k the rate constant for the reaction, $\hat{\rho}_0$ the equilibrium density

matrix, and $\hat{\rho}_{\text{dg}}(t)$ and $\hat{\rho}_{\text{od}}(t)$ the diagonal and off-diagonal parts of $\hat{\rho}(t)$ which are assumed to relax by respectively single longitudinal and transverse modes. Limiting ourselves to the homonuclei case the Hamiltonian, $\hat{\mathcal{H}}$, in the rotating coordinate system includes both single and binuclear terms,

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_Q + \hat{\mathcal{H}}_S \quad (2)$$

where

$$\hat{\mathcal{H}}_Z = - \sum_i \omega_0(1 - \sigma_i) \hat{I}_{iz} = \sum_i \omega_i \hat{I}_{iz} \quad (3a)$$

$$\hat{\mathcal{H}}_Q = \sum_i \omega_{Qi} [(\hat{I}_{iz})^2 - \hat{I}_i(\hat{I}_i + 1)/3] \quad (3b)$$

$$\begin{aligned} \hat{\mathcal{H}}_S = \sum_{i < j} \{ & 2(D_{ij} + J_{ij}^a) [\hat{I}_{iz} \hat{I}_{jz} - (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+})/4] \\ & + J_{ij} [\hat{I}_{iz} \hat{I}_{jz} - (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+})/2] \} \end{aligned} \quad (3c)$$

In these equations ω_0 and ω_i are the reference and resonance frequencies in the rotating frame, σ_i the motionally averaged chemical shift, ω_{Qi} the average quadrupole interaction, D_{ij} the average direct dipole-dipole interaction, and J_{ij}^a and J_{ij} are respectively the average anisotropic and scalar spin-spin couplings. The sum is over all magnetic nuclei in the molecule assumed to belong to the same isotope (homonuclei). The averaged anisotropic parameters, $T = \sigma_i$, ω_{Qi} , D_{ij} , J_{ij}^a , are related to their static tensorial components, $T_{\alpha\beta}$, in the molecular-fixed frame $\alpha, \beta = x, y, z$ via the so-called motional constants, C_α^2 .^{14,15} The liquid crystal is assumed to have a nonpolar cylindrical symmetry defined by a director which aligns parallel to the magnetic field. The molecular orientation distribution function can then be expanded in even orders of the (real) spherical harmonic functions

$$\begin{aligned} P(\theta, \phi) = \frac{1}{4\pi} + C_{3z^2-r^2}^2 D_{3z^2-r^2}^2 + C_{x^2-y^2}^2 D_{x^2-y^2}^2 \\ + C_{xz}^2 D_{xz}^2 + C_{yz}^2 D_{yz}^2 + C_{xy}^2 D_{xy}^2 + O(D^4) \end{aligned} \quad (4)$$

where the D_α^2 s are normalized so that $\int_0^{2\pi} \int_0^\pi D_\alpha^2 D_{\alpha'}^2 \sin \theta \, d\theta \, d\phi = (1/4\pi) \delta_{\alpha\alpha'}$

$$\left. \begin{aligned} D_{3z^2-r^2}^2 &= \left(\frac{\sqrt{5}}{4\pi} \right) \frac{1}{2} (3 \cos^2 \theta - 1) \\ D_{x^2-y^2}^2 &= \left(\frac{\sqrt{15}}{4\pi} \right) \frac{1}{2} (\sin^2 \theta \cos 2\phi) \\ D_{xy}^2 &= \left(\frac{\sqrt{15}}{4\pi} \right) \frac{1}{2} (\sin^2 \theta \sin 2\phi) \\ D_{xz}^2 &= \left(\frac{\sqrt{15}}{4\pi} \right) (\sin \theta \cos \theta \cos \phi) \\ D_{yz}^2 &= \left(\frac{\sqrt{15}}{4\pi} \right) (\sin \theta \cos \theta \sin \phi) \end{aligned} \right\} \quad (5)$$

and $C_\alpha^2 = 4\pi \int_0^{2\pi} \int_0^\pi P(\theta, \phi) D_\alpha^2 \sin \theta \, d\theta \, d\phi$. The averages of the anisotropic interactions are given by

$$\begin{aligned} T = \frac{1}{\sqrt{15}} \left\{ C_{3z^2-r^2}^2 \frac{2}{\sqrt{3}} [T_{zz} - \frac{1}{2}(T_{xx} + T_{yy})] \right. \\ + C_{x^2-y^2}^2 (T_{xx} - T_{yy}) + C_{xz}^2 (T_{xz} + T_{zx}) \\ \left. + C_{yz}^2 (T_{yz} + T_{zy}) + C_{xy}^2 (T_{xy} + T_{yx}) \right\} \end{aligned} \quad (6)$$

Molecular symmetry will reduce the number of nonzero motional constants by choosing the appropriate molecular coordinates x, y , and z .¹⁵

To calculate the time domain signal it is necessary to compute the expectation value of the transverse magnetization

$$M_+(t) = \text{Tr}(\hat{\rho}(t) \hat{I}_+) = \sum_{k,\ell} \rho_{k\ell}(t) (I_+)_{\ell k} \quad (7)$$

which upon Fourier transformation yields the frequency spectrum

$$I(\omega) = \text{Re} \int M_+(t) \exp(-i\omega t) \, dt \quad (8)$$

As $(I_+)_{\ell k} \propto \delta_{k,l-1}$ we only need off-diagonal elements of the density matrix of the type $\rho_{k,k+1}(t)$. Consequently, since the Hamiltonian is secular and the exchange operators only mix states of the same total azimuthal quantum number, m_l we extract from equation (1) those blocks of equations which couple between m_k and m_{k-1} states. For a spin system with N nuclei of spin $I = \frac{1}{2}$, there are N such blocks with dimensions

$$\begin{aligned} (N!)^2 / [(N/2 - m)!(N/2 + m)!(N/2 + 1 - m) \\ \cdot (N/2 - 1 + m)!] \end{aligned} \quad (9)$$

The largest blocks are the $0 \rightarrow \pm 1$ transitions for N even and the $-\frac{1}{2} \rightarrow +\frac{1}{2}$ transitions for N odd with dimensions

$$\frac{N}{N+2} \frac{(N!)^2}{[(N/2)!]^4} \quad \text{and} \quad \left(\frac{(N+1)}{2} \right)^2 \frac{(N!)^2}{[((N+1)/2)!]^4} \quad (10)$$

respectively. The general equation for the $m_k \rightarrow m_l$ manifold becomes

$$\begin{aligned} \frac{d}{dt} \rho_{kl}(t) = i \left[\sum_r \rho_{kr}(t) H_{rl} - \sum_i H_{ki} \rho_{il}(t) \right] \\ + k \left[\sum R_{kn} \rho_{nm}(t) (R^{-1})_{ml} - \rho_{kl}(t) \right] - \frac{\rho_{kl}(t)}{T_2} \end{aligned} \quad (11)$$

These equations can be cast into the following matrix form

$$\frac{d}{dt} \boldsymbol{\rho}(t) = \mathbf{L} \boldsymbol{\rho}(t) \quad (12)$$

where $\rho(t)$ is the vector of the $\rho_{kl}(t)$ quantities. The formal solution of $\rho(t)$ then becomes

$$\rho(t) = \exp(\mathbf{L}t)\rho(0) = \mathbf{T} \exp(\mathbf{\Lambda}t)\mathbf{T}^{-1}\rho(0) \quad (13)$$

where $\mathbf{\Lambda}$ is the diagonal matrix of the eigenvalues of $\mathbf{L}$ and $\mathbf{T}$ the matrix of its eigenvectors. From equation (10), it follows that the dimensions of the blocks corresponding to the $m = 0$ to $m = \pm 1$ or $m = \frac{1}{2}$ to $m = -\frac{1}{2}$ transitions for $N = 6, 7$, and 8 become $300, 1225$, and 3920 , respectively, rendering the calculation of such spectra rather time-consuming and prone to roundoff errors even on large mainframe computers.

Symmetry considerations can often be helpful in factorizing the blocks.^{16,17} To do so, the $\rho_{kl}(t)$ terms are calculated in bases of symmetry adapted linear combinations of spin product functions belonging to irreducible representations of the symmetry group of the static molecule.¹⁸ This reduces the dimension of the blocks to just the number of allowed transitions which depending on the symmetry of the molecule can be considerably smaller than given by equation (10). Further factorization is provided by the fact that the exchange operator usually couples only between a limited number of representations, in fact only between those representations that induce the same irreducible representation of the symmetry group of the exchange-averaged Hamiltonian.¹⁶ They can readily be determined by correlation diagrams relating the symmetries of the two groups. These symmetry considerations have in many cases very effectively reduced the size of the matrices that need be solved. For example, in the case of the bondshift reaction of cyclooctatetraene, the largest matrix that need be diagonalized in order to calculate the proton NMR spectrum in a liquid crystalline solution is 3920×3920 , while when symmetry considerations are included it reduces to 224×224 .

3 EXPERIMENTAL ASPECTS

3.1 Liquid Crystalline Solvents

So far only thermotropic nematic phases with positive anisotropic magnetic susceptibility, $\Delta\chi > 0$, i.e. which align with their director parallel to the magnetic field, have been used as solvents for dynamic NMR studies. The nematic phase is usually very fluid and consequently yields sharp-line spectra for dissolved solute molecules. The samples are contained in long cylindrical tubes as for high-resolution NMR of isotropic liquids. If a permanent magnet or an electromagnet with the magnetic field perpendicular to the tube axis is used, it is not allowed to spin the sample because the spinning smears out the director orientation and causes broadening of the spectrum. However, for superconducting magnets where the magnetic field is parallel to the sample axis, spinning usually sharpens the lines and increases the spectral resolution. The choice of solvent depends on the solubility of the solute, its degree of ordering, and the desired temperature range for the measurements. The solute concentrations range between 1–10 wt.%. Addition of solute usually reduces the clearing temperature but on the other hand it also often facilitates supercooling. Table 1 lists some common liquid crystals used in dynamic NMR studies with their nematic ranges.

For proton (and ^{13}C), NMR background signal may also be a consideration in the choice of solvent. For certain solutes, such as polar or hydroxylic compounds, lyotropic nematic phases may be the preferred choice as a solvent, but these have so far not been used for dynamic studies. Compounds exhibiting the uniaxial smectic A phase may also serve as adequate solvents. This phase, once aligned, for example, by cooling from a nematic or an isotropic phase within a magnetic field, will remain aligned in the sample holder even if rotated with respect to the field.¹⁹ This allows reduction of the frequency range of the spectrum if a small sweep width is desired. Smectic phases are however usually more viscous than nematic and in the presence of solutes often undergo phase separation.

3.2 NMR Measurements

Most dynamic NMR studies in liquid crystalline solvents have been performed on protons, carbon-13, and deuterons.^{20–38} The proton spectra are dominated by dipolar interactions and usually span several kHz. Carbon-13 dynamic studies have so far only been made^{24,25} under proton decoupling so that the spectrum depends on the chemical shift anisotropy which is of the same order as that of the isotropic shift in normal liquids. For deuterium NMR the dominant effect on the spectrum is due to the quadrupole interaction, which depending on the motional constants of the solute may extend up to several tens of kHz.

When the frequency range does not exceed about 5–10 kHz, adequate spectra can be obtained by single pulse experiments. For wider frequency ranges, echo experiments are required. This is particularly true for deuterium NMR, where the method of choice is that of quadrupole echo.³⁹ In such experiments the observed lineshape will depend on the time intervals between the pulses in the sequence. This is taken into account⁴⁰ in the simulation by repeated application of equation (13) for the time intervals, where the magnetization evolves freely and performing proper transformations of the density operators representing the rf pulses.

Temperature stability and homogeneity are crucial for obtaining high-resolution spectra. Because of the sensitivity of the orientational order to temperature, small gradients may cause excessive line broadening and corresponding loss of resolution. Imperfect alignment may also be a source for loss of resolution. This is caused by the fact that different domains have slightly different orientations and accordingly slightly different splittings. The effect is often manifested by progressive line broadening for peaks which are further removed from the spectrum center.

4 APPLICATIONS TO SPIN $I = \frac{1}{2}$ NUCLEI

Several applications of high-resolution proton NMR in liquid crystalline solutions have been published and here we describe two such cases. Dynamic ^{13}C spectra recorded under proton decoupling will also be reviewed. The emphasis is on systems for which kinetic information was derived from a lineshape analysis, rather than on dynamic equilibria between species in the extreme fast regime.

Table 1 Nematic Liquid Crystals Used as Solvents for NMR Studies of Solute Molecules

Brand name or acronym	Chemical name and/or composition	Nematic range (°C)
DHAB	4,4'-dihexyloxyazoxybenzene	84–127
TBBA	terephthalaldehyde-bis(4- <i>n</i> -butylaniline)	199–233
S 1131 BCH	<i>trans</i> -4-pentyl-1-(4'-cyanobiphenyl-4)-cyclohexane	96–222
10836	<i>p</i> -(<i>p</i> -ethoxyphenylazo)phenyl crotonate	109–194
Phase V	eutectic mixture of (two isomers each): <i>p</i> -ethoxy- <i>p</i> '-butyloxyazoxybenzene <i>p</i> -methoxy- <i>p</i> '-butyloxyazoxybenzene	5–75
ZLI 2452	mixture of derivatives of cyanophenylcyclohexane, cyanobiphenylcyclohexane, and unspecified esters	–40–110

4.1 Ring Inversion of *s*-Trioxan

The rate of the ring inversion of *s*-trioxan (Scheme 1) was studied by proton NMR in isotropic solutions.⁴¹ The chemical shift difference between the axial and equatorial protons and their spin–spin coupling are quite small (0.093 ppm and 6.3 Hz, respectively), while the rate of the process at room temperature is rather high. It was therefore necessary to cool the solutions to below –50 °C to obtain dynamic spectra. When the compound is dissolved in a nematic

solvent the spectrum is dominated by the dipolar interactions and its spectral width is considerably larger. Above about 70 °C it exhibits sharp peaks with splittings corresponding to the average dipolar interaction of the two conformations.⁴² However on cooling to room temperature and below, the lines broaden because the exchange rate becomes of the order of the dipolar interactions.²² Examples of spectra are shown in Figure 1. Note that the spectra were recorded in two different nematic solvents which give different background signals. The

Figure 1 Left: Experimental proton NMR spectra of solutions of *s*-trioxan in liquid crystalline solvents at various temperatures. The solvent used was phase V (2.8 wt.%), except for the 79 °C spectrum which corresponds to a 2.0 wt.% solution in DHAB. Note the different background signals for the two liquid crystal solvents. Right: Corresponding simulated spectra, calculated using the indicated rate constants and the magnetic parameters given in Table 2 with a fixed motional constant $C_{3z^2-r^2}^2 = -0.2$

Scheme 1

Table 2 Parameters Used in the Simulation of the *s*-Trioxan Spectra in Figure 1

$J_{14} = 6.3 \text{ Hz}$	$D_{12} = D_{13} = D_{23} = C_{3z^2-r^2}^2 3941.6 \text{ Hz}$
$\sigma_{ae} = 0.093 \text{ ppm}$	$D_{14} = D_{25} = D_{36} = C_{3z^2-r^2}^2 (-9651.26) \text{ Hz}$
	$D_{45} = D_{56} = D_{46} = C_{3z^2-r^2}^2 775.59 \text{ Hz}$
$D_{15} = D_{16} = D_{24} = D_{26} = D_{34} = D_{35} = C_{3z^2-r^2}^2 499.28 \text{ Hz}$	

spectra were simulated using equation (11) with magnetic and kinetic parameters as given in Table 2 and in Figure 1. For simplicity a fixed motional constant was used for displaying the calculated spectra. The dipole–dipole, indirect spin–spin, and chemical shift interactions were determined from low-temperature spectra in isotropic solutions and high-temperature spectra in liquid crystalline solvents. The anisotropic chemical shift and the anisotropic indirect spin–spin coupling were neglected. Since the molecule has threefold symmetry only one motional constant, $C_{3z^2-r^2}^2$, is required. Its value can be obtained from the line splittings, in particular from the so-called dynamically invariant lines, i.e. lines that remain sharp throughout the dynamic range. These lines correspond to transitions that are not modulated (or nearly not modulated) by the dynamic process. Such lines are the two $\pm 1 \rightarrow 0$ pairs of A_2 symmetry clearly seen in the low-temperature spectra of Figure 1. Inspection of the eigenfunctions²² between which these transitions occur shows that the exchange-induced permutation of nuclei does not change the dipolar interactions of either the initial or final states. The chemical shift on the other hand is modulated by the exchange, but the effect is small and is averaged out already at much lower temperatures than those for which spectra are depicted in Figure 1.

The derived rate constants for the ring inversion reaction are plotted in Figure 2. The figure demonstrates one of the main advantages of the method, i.e. the large dynamic range over which measurements can be made. The lower bound of the dynamic range (10^4 s^{-1}) in this experiment was set by the lack (at the time) of suitable nematic liquids for high-resolution measurements below -20°C . Also depicted in Figure 2 are the results obtained in an isotropic solvent. These correspond to rates which are orders of magnitude slower than those obtained in the nematic solvent and span a much smaller dynamic range. It may be seen however that both sets of data fit a single Arrhenius line. This indicates that within the accuracy of the experiment the kinetic parameters for the reaction are not very sensitive to the solvent, not even on going from an isotropic to a nematic solvent. This is not surprising for a ring-inversion process, since its rate is predominantly determined by the internal coordinates of the molecule. In other cases, where solute–solvent interactions play a role or for bimolecular reactions where ordering effects are important, the situation may be different.

**Figure 2** Arrhenius plot of the rate constant for the ring inversion of *s*-trioxan in liquid crystalline (circles) and isotropic (triangles) (Freon) solvents. The circles above 60°C correspond to solvent DHAB while those below to phase V

4.2 Bond Shift in Cyclooctatetraene (COT)

As a second example we consider the bond shift process in COT (Scheme 2). This molecule has D_{2d} symmetry rendering all eight protons of the molecule equivalent. Consequently the proton NMR spectrum in an isotropic solvent consists of a single line and is not useful for dynamic measurements. The bond shift reaction could therefore only be studied in substituted molecules and in a qualitative manner from the ^{13}C spectrum.^{43,44} The proton NMR spectrum of COT in a liquid crystalline solvent on the other hand is highly structured, reflecting the dipolar interactions between all protons in the molecule and exhibits dynamic effects as the temperature is raised from below -20°C to well above 100°C .²¹ Examples of spectra are depicted in Figure 3. The ‘static’ spectrum at -25°C could readily be interpreted with the parameters summarized in Table 3. On heating to above -25°C line broadening sets in and at room temperature only a number of invariant (or almost invariant) lines are observed. Above 100°C the spectrum coalesces yielding at 170°C a pattern corresponding to the averaged dipolar interactions. Simulation of such dynamic spectra would require, without the use of

Scheme 2

Figure 3 Left: Experimental proton NMR spectra of COT in liquid crystalline solvents at different temperatures. The solvents were: for -25°C to 20°C , phase V; for 40°C , 'Nematic Mixture'; 70°C and 105°C , DHAB; and for 170°C , TBBA. Right: Simulated spectra calculated with the indicated rate constants and the magnetic parameters given in Table 3. A fixed motional constant was used for all the simulated spectra. The spacings between the markers on the left are 500 Hz for the bottom four spectra, 250 Hz for the next three and 125 Hz for the topmost one. On the right, the spacings are 1000 Hz for the bottom four traces and 500 Hz for the four upper ones

symmetry, the diagonalization of matrices as large as 3920×3920 . When symmetry considerations are included¹⁶ and group theoretical methods are applied to factorize the matrices, the largest block becomes 224×224 . This in fact made the problem solvable in practice,²³ as shown by the simulated spectra in the right column of Figure 3.

In the original work on the NMR spectrum of COT in liquid crystalline solutions²¹ dynamic information was derived from proton spectra of almost but not completely deuterated COT. The isotopic mixture contained a relatively large fraction of $\text{C}_8\text{D}_6\text{H}_2$ isotopomers, each yielding at slow exchange a single doublet. From the initial broadening of the peaks and from the width of the lines in the fast exchange region, estimates

Table 3 Magnetic Parameters of COT used in the Simulation of the Dynamic Spectra Depicted in Figure 3

D_{12}	-1620.3
$D_{13} = D_{17}$	-103.8
D_{14}	-84.5

of the rate parameters for the bond shift process were derived. The use of such incompletely deuterated samples to obtain simplified proton spectra was found helpful in many structural studies of solute molecules.^{45–48} To eliminate broadening due to dipolar interactions with the deuterons, a special decoupling technique was designed involving saturation of the deuterium double quantum transition.^{45,46} This requires much less rf power and eliminates sample heating problems.

4.3 Hindered Rotation Measurements

Dynamic NMR has also been applied to natural-abundant ^{13}C of solute molecules dissolved in liquid crystals as demonstrated by Fung et al.²⁴ Since such spectra are extremely weak and are often masked by the more intense solvent peaks, they were recorded under proton decoupling conditions. The spectra are then essentially identical to those in isotropic solutions except that the chemical shift is modified by the solute ordering. To reduce the interference effect of the solvent signals, special spin echo sequences were used to take advantage of the shorter T_1 values of the nematic solvent carbons, but even then special solvents with ^{13}C windows at the solute frequencies had to be used.

Further simplification may be achieved by using magic angle spinning.²⁵ For $\Delta\chi > 0$ solvents the director aligns along the spinning axis and the spectrum becomes identical to that in an isotropic solvent. Under these conditions, there is no advantage in using a liquid crystalline solvent, unless of course one wishes to study the effect of ordering on the dynamic process. The method was applied to several systems exhibiting hindered rotations; 4-(dimethylamino)pyrimidine and 6-(dialkylamino)fulvenes. The main conclusion of the work confirms that within the experimental accuracy the ordering by the nematic solvent does not affect the kinetic parameters of the process.

5 MULTIPLE QUANTUM DYNAMIC NMR FOR SPIN $I = \frac{1}{2}$ NUCLEI

The proton NMR spectra in liquid crystalline solvents for molecules with 10 or more hydrogens are so rich in lines that they become structureless with few features that can be used for quantitative analysis. The difficulty can partially be resolved by employing the method of multiple quantum spectroscopy. In such experiments one displays $\Delta m > 1$ spectra which involve less transitions than the corresponding ordinary $\Delta m = 1$ spectra, and are therefore better resolved and more convenient for comparison with calculations.⁴⁹ As for

Figure 4 Experimental 2D fourth quantum order contour plot for a solution of *s*-trioxan (2.7 wt.%) in phase V at 17 °C using the SMQ experiment. The one-dimensional spectra along ν_1 and ν_2 are skyline projections and correspond respectively to fourth and single quantum order transitions

single quantum spectra these also exhibit line broadening and coalescence effects. They cannot be detected by ordinary pulse NMR, but can be obtained by several indirect ways which usually involve 2D methods. Two methods were considered for dynamic proton NMR in liquid crystalline solvents. The time proportional phase increment (TPPI) sequence⁵⁰ was employed for simulating²⁶ dynamic multiple quantum spectra and, subsequently, a simpler version⁵¹ which allows recording a particular single multiple quantum (SMQ) spectrum was used.²⁷ We refer to the literature^{26,27} for the theoretical background and confine ourselves here to briefly reviewing experimental results obtained in liquid crystalline solutions.

In Figure 4 a 2D plot of the proton SMQ spectrum of a solution of *s*-trioxan recorded at 17 °C is displayed²⁷ together with skyline projections along ν_1 (the evolution coordinate) and ν_2 (the detection coordinate). The latter is a $\Delta m = 1$ spectrum but the much simpler ν_1 projection corresponds to the fourth quantum order. Similar fourth quantum projection spectra recorded at different temperatures are presented in Figure 5. These are compared with simulated spectra which were computed by two methods; exact calculation employing the full density matrix formalism and approximate methods. The latter are the density matrix analogs for the slow (bottom trace) and fast (all other traces) exchange regimes. No adjustable parameters were used in the calculations (except for the order parameter), rather the known rate constants and magnetic parameters from earlier studies were adopted. As may be seen, the fit of the experimental and simulated spectra is quite satisfactory. It should be noted however that despite the simple appearance of the MQ spectra their simulations are as complicated as those for the single quantum spectra. This is so because for the calculations it is necessary to follow the evolution of a multitude of coherences. Fortunately,

approximate methods exist²⁶ that are much simpler and as may be seen in Figure 5 they result in spectra very similar to those calculated by the exact method.

6 DYNAMIC NMR FOR SPIN $I = 1$ NUCLEI

Of the nuclei with spin $I = 1$, deuterium is the most important for dynamic NMR studies in nematic solvents. However due to its low natural abundance it is necessary to work with isotopically enriched samples. This might require special skills, but techniques are available that allow complete or selective deuteration of many compounds.⁵² The method has several advantages; the spectrum is free of background signals and is usually very simple. The dipolar interactions between the deuterons or with other nuclei (protons) are usually within the linewidths, and the structure of the spectrum is predominantly due to the much larger quadrupole interaction. For spin $I = 1$ nuclei, this corresponds to a single doublet for each type of nucleus, and thus the deuteron spectrum of a deuterated solute in a nematic solvent consists of a number of doublets according to the number of inequivalent deuterons in the molecule. The simulation of dynamic spectra then requires only the solution of Bloch–McConnell type equations rather than the full density matrix equations. In the absence of chemical shift effects, the spectrum of the $m = -1$ to $m = 0$ manifold is the mirror image about the center frequency of the $m = 0$ to $m = +1$ manifold. A third advantage is the large dynamic range that can be studied by deuterium NMR. Since the splitting can be as high as several dozens of kHz, the upper limit of the dynamic range may be considerably higher than that for protons.

6.1 Ring Inversion in Cyclohexane and *p*-Dioxan

As a simple example where the advantages of dynamic deuterium NMR in nematic solvents are well demonstrated, consider the ring inversion process in cyclohexane- d_{12} (C_6D_{12}) (Scheme 3). Experimental spectra²⁸ are depicted in the left column in Figure 6. At low temperatures the spectrum consists of two doublets due to the axial (outer doublet) and equatorial (inner doublet) deuterons with a relative splitting of ~ 3 . The quadrupole interaction for aliphatic deuterons are nearly constant at $\nu_Q^s \approx 125$ kHz (as compared to ~ 140 kHz for aromatic deuterons) with cylindrical symmetry about the C–D bond. Accordingly the average quadrupole splitting for a molecule with threefold symmetry, such as cyclohexane, will be proportional to $\nu_Q^s \frac{1}{2}(3 \cos^2 \beta - 1)$ where β is the angle between the C–D bond and the molecular symmetry axis. For the axial and equatorial deuterons in cyclohexane, this corresponds to $\langle \nu_Q^{ax} \rangle / \langle \nu_Q^{eq} \rangle \sim -3$ as observed experimentally. In the dynamic spectra the opposite signs of the $\langle \nu_Q \rangle$ quantities is reflected in the mixing of the high-frequency axial

Scheme 3

Figure 5 Experimental (left) and calculated (center and right) fourth order quantum spectra of *s*-trioxan solutions in phase V. The experimental spectra were obtained as in Figure 4, the spectra in the middle column were calculated by the exact density matrix formalism, those in the right column were calculated by approximate methods

Figure 6 Experimental (left) and simulated (right) deuterium NMR spectra of cyclohexane- d_{12} (3.6 wt.%) in phase V. The overall frequency range corresponds to 83.3 kHz for the lowest three traces and 50.0 kHz for the upper four

peak with the low-frequency equatorial peak and vice versa. This is clearly observed in the experimental spectra depicted in Figure 6 and in the corresponding simulated traces. The spectra correspond to inversion rates ranging from 10^3 s^{-1} to almost 10^6 s^{-1} , and when semilogarithmically plotted as a function of the inverse absolute temperature a straight Arrhenius line is obtained which extrapolates perfectly through the results obtained in isotropic liquids at much lower temperatures.⁵³ In the simulation of the spectra the order parameter, $C_{3z^2-r^2}^2$, must be known. In the low- and high-temperature regions, where sharp peaks are observed, this parameter can be calculated from the line splitting and by interpolation the values at the intermediate range can be derived.²⁸

As a second example we consider the case of *p*-dioxan (Scheme 4). This molecule has C_{2h} symmetry and therefore three motional constants are required to describe its orientation in a liquid crystalline solvent. The average quadrupole splitting is given by

$$\langle \nu_Q^i \rangle = \nu_Q^s \sqrt{\frac{3}{5}} \left[\frac{1}{\sqrt{3}} C_{3z^2-r^2}^2 \frac{1}{2} (3 \cos^2 \beta^i - 1) + C_{x^2-y^2}^2 \frac{1}{2} \sin^2 \beta^i \cos 2\alpha^i - C_{xy}^2 \frac{1}{2} \sin^2 \beta^i \sin 2\alpha^i \right] \quad (14)$$

where β^i and α^i are the polar and azimuthal angles of the C-Dⁱ bond in the molecular coordinate system x, y, z with

Scheme 4

z perpendicular to the symmetry plane of the molecule. The motional constants are independent and their ratios vary with temperature and from solvent to solvent. Therefore there is no a priori relation between the quadrupole splittings of the axial and equatorial deuterons as is in cyclohexane. In particular their relative sign can be both positive and negative.

The *p*-dioxan molecule undergoes ring inversion in a similar fashion to cyclohexane⁵³ and the reaction was studied by deuterium dynamic NMR in two nematic solvents, phase V and 1565 TNC.²⁹ Experimental spectra are shown in the left columns of Figure 7. As may be seen, their evolution with temperature is quite different and this has been interpreted as due to different relative signs of the axial and equatorial

Scheme 5

quadrupole interactions (same signs in phase V and opposite signs in 1565 TNC). When this effect is taken into account, satisfactory simulation of both sets of spectra are obtained as shown in the right columns of Figure 7. The derived rate constants for the ring-inversion process were found to be identical in both solvents.

The spectra shown above for C_6D_{12} and $C_4O_2D_8$ (Figures 6 and 7) were recorded by single pulses and are therefore distorted due to the dead-time effect. In subsequent works this problem was resolved by using the quadrupole echo method. The spectrum is then also a function of the time interval between the pulses and this must be included in the simulation.⁵⁵

Figure 7 (a) Experimental and simulated deuterium NMR spectra of *p*-dioxan- d_8 dissolved in phase V. The overall frequency scale is 50 kHz for the bottom three spectra and 20 kHz for the top two. In the simulation identical signs of the quadrupole interactions were assumed for the axial and equatorial deuterons. (b) Same as in (a) but for a solution in 1565 TNC. The overall scale is 100 kHz for the bottom three traces and 20 kHz for the top two. In the simulation, opposite signs for the axial and equatorial deuterons were assumed

6.2 Cope Rearrangement in Bullvalene

Bullvalene undergoes fast Cope rearrangement (Scheme 5) and this process has been extensively studied by 1H and ^{13}C NMR in isotropic solutions.⁵⁴ The reaction is highly degenerate and results in complete equivalence of all the carbons and all the hydrogens in the molecule. Proton spectra of bullvalene dissolved in a nematic solvent were also recorded⁵⁶ but only at high temperatures where they correspond to the fast exchange limit. More extensive studies involving liquid crystalline solutions were made by deuterium NMR.³⁰ At low temperatures the spectrum consists of four doublets with relative intensities 3:3:3:1 [see Figure 8(a)]. The identification of the outer peaks with deuteron number 4 is straightforward while the other peaks were identified from the known structure of the molecule. The spectrum shows a small asymmetry which is due to the fact that the olefinic deuterons have a slight high-frequency shift relative to the aliphatic ones. At high temperatures [upper trace in Figure 8(a)] the spectrum coalesces into a single doublet, reflecting the fact that all deuterons become equivalent. In the intermediate temperature range typical dynamic spectra are observed, Figure 8(b), that could readily be simulated as shown in Figure 8(c). The deuterium quadrupolar couplings, ν_Q^i , used for the simulation of the dynamic spectra are listed in Table 4 in units of the largest splitting, ν_Q^4 . The good fit between the experimental and simulated spectra confirms the high degeneracy of the Cope rearrangement. A more direct confirmation of the kinetic pathway was obtained by the two-dimensional exchange method described in the next section.³³

Figure 8 (a) Experimental deuterium NMR spectra of bullvalene- d_{10} dissolved in ZLI 2452 (3.8 wt.%) at -5 °C (lower trace) and in DHAB (4.7 wt.%) at 114.3 °C (upper trace). The diagram at the top indicates the different orders of exchange by the Cope rearrangement. Double arrow, full line, and dashed line correspond to first-, second-, and third-order exchanges. (b) Experimental dynamic NMR spectra of bullvalene- d_{10} in phase V (5.7 wt.%) at the indicated temperatures. (c) Simulated dynamic spectra calculated using the indicated rate constants and the relative quadrupole interactions given in Table 4. For each spectrum, a suitable motional constant was chosen³⁰

7 TWO-DIMENSIONAL EXCHANGE NMR SPECTROSCOPY FOR SPIN $I = 1$ NUCLEI

Two-dimensional (2D) exchange NMR was introduced by Jeener et al. to study slow exchange processes for spin $I = \frac{1}{2}$ nuclei.⁵⁷ The method was subsequently extended to deuterons ($I = 1$) in solids and ordered systems in general by Spiess and collaborators.^{58–60} It is most useful in the dynamic window for which $1/T_1 \lesssim k < 1/T_2$ and has also found interesting application in liquid crystalline solutions of deuterated solutes. Some of these will be described below.

The basic scheme of the experiment consists of three pulses (Scheme 6).³¹ Following the first 90° pulse (P_1) which takes the magnetization to the transverse plane, the various nuclei precess according to their quadrupole interactions and are thus phase-encoded. A second θ pulse (P_2) then produces either Zeeman or quadrupole order depending on the relative phases ($\phi_1 - \phi_2$) of the two pulses. These longitudinal magnetizations are allowed to undergo exchange during a preset mixing time, τ_m , following which a third pulse (P_3) takes them back to the transverse plane and the signal is detected as a function of the detection period t_2 . To obtain pure 2D

exchange spectra, signals from Zeeman and quadrupole order experiments are combined with appropriate relative intensities, so as to eliminate nonexchange off-diagonal peaks. Two-dimensional Fourier transformation then produces a 2D map with peaks corresponding to the one-dimensional spectrum along the main diagonal and exchange cross peaks off the main diagonal. These cross peaks link between sites i, j which interchange by the exchange process. Their intensity is proportional to

$$I_{ij} = P_i [\exp(kK\tau_m)]_{ij} \exp(-\tau_m/T_1) \quad (15)$$

where P_i is the equilibrium population of site i , and k and K are respectively the rate constant and the exchange matrix for the process. The experiment has several important advantages; measurements can be made in a dynamic range inaccessible by the lineshape method; the cross peaks directly identify the interchanging sites and thus the mechanistic pathway of the process; the cross peaks provide information on the relative signs of the quadrupole interactions of the interchanging sites, and from their evolution with τ_m kinetic parameters may be derived.

Scheme 6

7.1 Peak Assignment and Relative Signs of Quadrupole Interactions

An example where some of the points mentioned in the last paragraph are demonstrated is that of *p*-dioxan-*d*₈ already discussed²⁹ in Section 6.1. It was pointed out there that the signs of the quadrupole interactions of the axial and equatorial deuterons are the same when *p*-dioxan is dissolved in phase V and the opposite in 1565 TNC. This is clearly seen in the exchange 2D spectra³¹ in Figure 9, where for phase V the cross peaks link separately the high-field and the low-field signals of the axial and equatorial deuterons, while in 1565 TNC a low-field axial peak is linked with a high-field equatorial peak and vice versa.

An application of the 2D exchange method which was essential for the peak assignment, is that of perdeuterated *cis*-decalin.³⁴ The molecule undergoes ring inversion (Scheme 7)⁶¹ and in liquid crystalline solutions exhibits temperature dependent dynamic spectra as shown in the left column of Figure 10. To simulate the spectra it is necessary to identify the peaks with particular deuterons in the molecule, or at least to identify the interchanging pairs of peaks. This can readily be done for deuterons 1,1' which are bonded to the tertiary carbons and remain invariant to the dynamic process. However for all other lines the assignment is not trivial. Since the molecule has *C*₂ symmetry, three motional constants are required to describe the ordering of the molecules [equation (14)] and the assignment cannot be made simply from a knowledge of the molecular structure. The problem was resolved by 2D exchange spectroscopy.³⁴ A 2D spectrum recorded at -5 °C is shown in Figure 11 where cross peaks linking pairs of diagonal signals are clearly observed. Although this does not completely assign the peaks, it does identify the signals which interchange by the ring-inversion process. Using this information, dynamic spectra could be simulated which satisfactorily reproduce the experiments as shown in the right-hand column of Figure 10. Other examples where 2D exchange provided assignment and even identified hidden peaks masked by strong signals include 1,1- and 1,4-dimethylcyclohexane.³⁸

Figure 9 Two-dimensional deuterium exchange spectra on solutions of *p*-dioxan-*d*₈ dissolved in phase V (left) and 1565 TNC (right). The spectra were taken at -43 °C with a mixing time $\tau_m = 1$ ms. Note that the signs of the quadrupole interactions of the two exchanging deuterons is the same in phase V and the opposite in 1565 TNC

Scheme 7

7.2 Cope Rearrangement In Bullvalene: Higher Order Cross Peaks

Most examples of monomolecular exchange phenomena involve twofold degeneracy, i.e. interchange between two configurations. In the 2D exchange spectrum this is manifested by cross peaks linking separate pairs of lines. The bullvalene molecule provides an example of a high degree of degeneracy where a diagonal peak can be linked by the exchange to more than one other signal. Consequently at longer mixing times, when two or more exchange steps occur, higher order cross peaks between signals not directly connected by the exchange process may show up.

This is demonstrated³³ in the 2D exchange spectra of bullvalene depicted in Figure 12. For a mixing time of 2 ms only first-order cross peaks are observed [see diagram in Figure 8(a)], i.e. between peaks directly linked by a single Cope rearrangement. At 5 ms an additional second order cross peak appears (1, 2) which is linked by two successive rearrangement steps, while at 10 ms even a third-order cross peak (4, 2) may

Figure 10 Experimental (left) and simulated (right) deuterium spectra of *cis*-decalin-*d*₁₈ in liquid crystalline solvents. The bottom three traces correspond to the solvent ZLI 2452 while the upper four to S 1131 BCH. The separation between the frequency markers corresponds to 10 kHz for the bottom three traces and to 5 kHz for the top four

Figure 11 A two-dimensional deuterium-exchange spectrum of a solution of *cis*-decalin-*d*₁₈ in ZLI 2452 at -5°C . The dashed lines identify the interchanging peaks due to ring inversion. The assignment of the peaks based on the 2D spectra and other considerations are indicated on the 1D spectrum above

be identified. Expanding equation (15) in powers of τ_m gives

$$I_{ij} = P_i[\delta_{ij} + kK\tau_m + \frac{1}{2}k^2K^2\tau_m^2 + \frac{1}{6}k^3K^3\tau_m^3 + \dots]_{ij} \quad (16)$$

where for the case of bullvalene

$$K = \begin{bmatrix} -1 & 0 & 2/3 & 1/3 \\ 0 & -1/3 & 1/3 & 0 \\ 2/3 & 1/3 & -1 & 0 \\ 1 & 0 & 0 & -1 \end{bmatrix} \quad (17)$$

Computation of K^2 and K^3 shows that indeed the element 1, 2 which is zero in K is nonzero in K^2 while an entry at 4, 2 appears only at K^3 and higher powers of K . In the short τ_m approximation, second- and third-order peaks should therefore increase as τ_m^2 and τ_m^3 , while first-order cross peaks (and the diagonal peaks) should increase (decrease) linearly. This is indeed confirmed experimentally.

8 DYNAMIC ECHO TRAIN EXPERIMENTS

In some cases dynamic spectra can only be obtained in the fast exchange regime, e.g. when the rate is fast and the activation energy too low to reduce it effectively to the intermediate and slow-exchange limit by cooling. Kinetic data can then be obtained by transverse relaxation studies but the

Figure 12 Two-dimensional deuterium exchange spectra of bullvalene- d_{10} dissolved in ZLI 2452 at 5°C for several mixing times as indicated in the figure. The dashed lines connect first-, second-, and third-order cross peaks in respectively the upper, middle and bottom spectra

Figure 13 Semilog plots of the echo intensity versus time in quadrupole echo train experiments performed on a solution of C_6D_{12} in phase V (7 wt.%) at 12.2°C for different pulse repetition rates as indicated

calculation requires knowledge of the magnetic interactions. When these are not known, ordinary relaxation data are not very useful. However when the transverse relaxation is measured by the Carr–Purcell sequence, or for spin $I = 1$ in liquid crystalline solvents by its quadrupole echo train analog, a determination of the rate constant can still be made if the time interval, τ , between the pulses is of the order of the mean lifetime between exchanges. In the fast-exchange regime, the transverse relaxation rate, as measured by the echo decay, is then also a function of the ratio of the exchange and pulse repetition rates.⁶² For deuterons jumping between two sites of equal populations the contribution to the decay rate of the echoes in a quadrupole echo train experiment becomes^{32,35}

$$\frac{1}{T_{2e}} = \frac{(\Delta\omega_Q)^2}{8k} \left[1 - \frac{\tanh(2k\tau)}{2k\tau} \right] \quad (18)$$

where $\Delta\omega_Q = \omega_Q^A - \omega_Q^B$ is the difference between the quadrupole splittings of the nuclei at the two sites.

The method was demonstrated³² for the case of ring inversion of C_6D_{12} in the nematic phase V between 0°C and the clearing temperature. Experimental echo intensities at 12.2°C for different time intervals between pulses are depicted in Figure 13 and the dependence of the decay rate, $1/T_{2e}$ on the pulse repetition rate, $1/\tau$, is plotted in Figure 14 for several temperatures. Analysis of these data in terms of equation (18) yields results for k that are in good agreement with those derived from the ordinary lineshape analysis.

The method was subsequently extended to the intermediate and slow-exchange regime³⁵ and although not very often used it has been successfully applied to study the self-diffusion in the plastic phase of succinonitrile.⁶³

1 INTRODUCTION

Conventional crystallographic representations of molecules in solids give the impression that the molecules are held rigidly in place in the crystal as static motionless bodies. However, molecules and their component groups and atoms are certainly not motionless in solids. Molecules in solids are dynamic entities with a wide range of different molecular motion types.

Although most types of molecular motion are generally slower in solids than in liquids, they may have an important role in determining the macroscopic properties of solid materials. This applies to all solids irrespective of their degree of crystallinity. For example, the mechanical properties of important materials such as polymers are closely related to their microscopic structures and molecular motions. In addition, the conductivity of solid polymer electrolytes and the electrical properties of conducting polymers originate from motions at the molecular level. It becomes important, therefore, to gain an understanding of the nature of these motions in all types of solids and their relative rates and activation energies.

Several physical techniques can be employed to examine these molecular dynamics including the measurement and interpretation of anisotropic displacement parameters from diffraction techniques, Raman scattering, Brillouin scattering and dielectric relaxation. However, the most versatile technique is NMR spectroscopy. NMR is particularly powerful because by judicious choice of the nucleus to be observed and the NMR technique to be employed a wide range of time scales for molecular motions are available.¹ A general rule of thumb is that if the frequency, or time scale for a nuclear interaction is similar to that of the molecular process occurring, the molecular process will modulate the NMR interaction, which

will give rise to an observable effect in most cases. Since many more NMR interactions are present in solids than in solution (where they are averaged to zero by rapid isotropic molecular tumbling) observation of molecular motions in solids is greatly facilitated. Moreover, both broad line (static samples) and high resolution (magic angle spinning) methods are available. Such processes have included, but are not restricted to, rotations or displacements of whole molecules; segmental motions in polymer chains; conformational dynamics in molecules such as bond rotations, ring inversions and pseudorotations; molecular rearrangements such as sigmatropic rearrangements and dynamic tautomerism; and hydrogen bond exchange processes.

An alternative way in which NMR can be used to measure the kinetics of molecular processes is to create a magnetic label at one site (chemical shift) and watch it being transferred to another. Such methods include inversion and saturation transfer and 2D EXSY spectroscopy. These measurements are made in real time and consequently their time scale is dependent on the nuclear relaxation times involved. This article reviews several diverse applications of solid-state NMR spectroscopy falling into the categories described above. Table 1 summarizes the major methods, their origins, and the typical rate ranges that they can be employed to study.

It is interesting to compare the kinetics of processes happening in the solid state with those observed in solution. In many cases involving conformational rate processes the rates in solids are considerably slower than those observed in solution. This is because of the additional constraints imposed upon such process by the neighboring molecules in the lattice. These constraints are not present in solution leading to lower energies of activation. This effect has been referred to as the principal of least distress.³ On the other hand for intramolecular tautomerization processes in which hydrogen atoms travel short distances such effects are negligible.

2 LINE SHAPE METHODS

Line shape methods have been used extensively in high resolution solution state NMR for many years, and are also available in solids under conditions of magic angle spinning (MAS). In particular ^{13}C CP/MAS NMR has yielded much useful information. Line shape effects occur in the exchange region where the chemical shift difference between sites in a molecule is of the same order as the rate at which they are exchanging. The basic theory for these effects was given by McConnell,² and often the modified Bloch equations are used for line shape calculations. Many computer programs are available for line shape calculations.

(1)

Table 1 Widely used methods for studying dynamic processes in solids

Method	Approximate rate range	Outcomes
T_1	Near Larmor frequency 10^6 – 10^9 Hz	Frequency of motion
$T_{1\rho}$	Near spin lock frequency 10^3 – 10^6 Hz	Frequency and often mode of motion
Line shape	Near chemical shift difference 10 – 10^4 Hz	Frequency of motion
2D EXSY	Near $1/T_1$ 10^{-2} – 10 Hz	Frequency of motion
Magnetization transfer	Near $1/T_1$ 10^{-2} – 10 Hz	Frequency of motion
^2H quadrupole echo spectra	Near quadrupole coupling constant 125 –kHz	Frequency and often mode of motion

Line shape changes due to dynamic effects in ^{13}C CP/MAS spectra are illustrated very simply in Figure 1.³ The changes arise from the *t*-butyl group rotation in (1). At low temperatures rotation of the *t*-butyl group is slow (i.e., rate of rotation is $\ll \delta\nu(\text{Hz})$) and three methyl resonances are seen. The coalescence of the three methyls into a single peak is observed at around 293 K ($\Delta G_c^\ddagger = \text{ca } 55 \text{ kJ mol}^{-1}$). The solution state coalescence takes place at approximately 183 K ($\Delta G_c^\ddagger = \text{ca } 38 \text{ kJ mol}^{-1}$). The lifting of the degeneracy of two of the methyl groups in solution is due to molecular dissymmetry in the crystal lattice. The increase in the activation energy by around 17 kJ mol^{-1} is due to the additional constraints imposed upon the process in the solid by the neighboring molecules.

An alternative, both in the nucleus employed and the result obtained, is seen in Figure 2.⁴ This shows the line shape changes in the ^{15}N CP/MAS spectra due to hydrogen exchange between the nitrogens in the porphyrin anion (2) encased in a solid matrix. In contrast to the example given above the degeneracy of the exchange seen in solution is not lifted in the solid state with only three ^{15}N resonances being observed. The rates of hydrogen transfer are very similar to those determined in solution. In this case there is no effect from neighboring molecules as the exchange is buried deep inside the molecule.

An example of six-membered ring inversion between two unequal sites is seen in Figure 3.⁵ In this case the dynamic spectral effects arise from ring inversion of cyclohexanol encased in a thiourea inclusion compound and were obtained by a ^{13}C single pulse MAS technique not CP/MAS. The smaller set of peaks in the low temperature spectra arise from the axial conformation. The free energy of activation for the ring inversion process (51 kJ mol^{-1} (eq to ax)) and the free energy difference (ca. 2.5 kJ mol^{-1}) are close to those observed for the compound in non-hydrogen bonding solvents (50 kJ mol^{-1} (eq to ax)) and (ca. 2.1 kJ mol^{-1}). Interestingly for several other mono-substituted cyclohexanes in thiourea inclusion compounds very different conformational parameters are obtained from those of the molecules free in solution.

In the above examples there were no spinning side bands in the high resolution solid state ^{13}C spectra. Where there is a spinning sideband manifold, line shape analysis in principle

requires consideration of the whole sideband pattern and not just the peaks at the isotropic chemical shifts. This is seen in a ^{13}C CP/MAS study of the sigmatropic Cope rearrangement of bullvalene in the solid state.^{6,7} Because the crystal structure of bullvalene as determined by X-ray crystallography is very highly ordered it was originally thought that the Cope rearrangement was not taking place in the solid. However, NMR studies have shown that in the solid state the molecule of bullvalene undergoes a sigmatropic rearrangement followed by a reorientation to regain the original molecular orientation in the solid. This process is given the rate constant k_c . Accompanying this process is a 3-fold rotation of the molecules as a distinct process given the rate constant k_r . These processes are shown in Figure 4 and the observed CP/MAS spectra are shown in Figure 5.

If the rotation were the only process the resonance for C4 would remain unaffected. The fact that this line broadens less rapidly than the others as the temperature is increased indicates the existence of the two processes and the line shape patterns at varying temperatures can be fitted to a process involving the two rate constants k_c and k_r . It should be noted that the spinning sidebands are observed for the superimposed resonances of C2 and C3 and that these form part of the coalescence pattern. Extracted Arrhenius activation energies for the Cope rearrangement and the three-fold rotation are found to be 63 and 88 kJ mol^{-1} respectively.

3 SPIN LATTICE RELAXATION TIME METHODS

Spin lattice relaxation, designated by the relaxation time T_1 , and relaxation in the rotating frame, designated by the relaxation time T_1 can form excellent probes for molecular motions in very different regions of molecular dynamics. The stimulation of NMR transitions at the heart of these relaxation processes occurs when the nucleus interacts with fluctuating fields inside the sample. There are two important fluctuating fields. The first is a fluctuating magnetic field that can interact with the nuclear magnetic moment. The second is a fluctuating electric field gradient (EFG) that can interact with the electric quadrupole moment of the nucleus (if it possesses one). Only quadrupolar nuclei ($I > 1/2$) have electric quadrupole moments. In all cases the frequency of the fluctuating field must be at or close to the field in which the nuclei are held. In addition, the exchange process to be studied must be the exclusive or principal cause of the nuclear relaxation.

For heteronuclei three cases can be identified: (i) static powders, (ii) powders being spun at the magic angle, and (iii) powders where longitudinal relaxation is isotropically

Figure 1 125.758 MHz ^{13}C line shape changes at variable temperature for (1) in the solid (CP/MAS) (lower set) and solution states. The changes are due to rotation of the *tert*-butyl group. Reproduced with permission from Ref.⁵

Figure 2 Line shape changes in the 9.12 MHz ^{15}N CP/MAS spectra of (2) at variable temperature. The changes are due to hydrogen exchange between the nitrogens in the porphyrin anion. Reproduced with permission from Figure 5 in Ref.⁴

averaged by magnetization transfer. In (i) relaxation is multi-exponential and consequently difficult to evaluate. In (iii) relaxation is truly exponential with a single relaxation time T_1 , which is related in a straightforward way to the dipolar interaction(s) and the equilibrium and rate constants, but this is experimentally very difficult to obtain. In contrast (ii) represents an ideal compromise – relaxation is quasi exponential and is governed to a good approximation by the dipolar interaction(s), rate and equilibrium constants. Rates of ultrafast exchanges can be measured by this technique. For example, this technique was employed by Hoelger et al.⁸ to study the hydrogen exchange dynamics in ^{15}N labelled dimethyldibenzyltetraaza[14]annulene (see Figure 6).⁸ The hydrogen transfer rates that were measured were in the range 10^6 – 10^8 s $^{-1}$.

Cross polarization is often used to generate the magnetization needed for T_1 measurements for ^{13}C or ^{15}N , for example. Under these circumstances the pulse sequence of Torchia is in widespread use.⁹ In this sequence for ^{13}C the ^{13}C magnetization is generated in an enhanced form by a cross polarization sequence and then an inversion recovery type sequence is used to follow the recovery of the magnetization as a function of time. During the evolution period the ^1H nuclei are decoupled by continuous phase irradiation to avoid the possibility of their dephasing the ^{13}C magnetization. The FID is then collected accompanied by high power ^1H decoupling.

For ^1H in organic solids the spins are strongly coupled via a spin diffusion process and consequently all have the same T_1 value. Thus no information about specific sites can be obtained even if separate peaks for these sites can be seen by special spectral techniques, for example CRAMPS.

Figure 3 125.758 MHz ^{13}C line shape changes due to ring inversion of cyclohexanol in a thiourea inclusion complex (single pulse MAS spectra). Reproduced with permission from Figure 2 in Ref.⁵

This greatly decreases the utility of ^1H T_1 measurements for characterizing molecular motions. They have, however, been applied in simple cases in which all the protons are equivalent such as molecular rotation in benzene.

For ^2H T_1 is the most unambiguous relaxation time as it depends exclusively on molecular motion. The relaxation of quadrupolar nuclei such as ^2H depends upon the interaction between the quadrupole moment of the nucleus and the electric field gradient it experiences. Fluctuating electric field gradients produce spin lattice relaxation of the ^2H nucleus and the correlation time for molecular motion can be inferred if details of the quadrupole interaction are known. Modulation of the electric field gradient in molecular solids is usually produced by rotational or segmental motions. This technique has proved of particular value in chain-like structures, e.g., polymers or lipids where selective deuteration along the chain can characterize the motion of different segments. Measurement of ^2H relaxation times for broad powder patterns can be troublesome and is often best achieved by a saturation recovery technique using the pulse sequence of Hirschinger et al.¹⁰

For powder samples, however, its interpretation is complicated by the anisotropy of T_1 because the relaxation time depends upon the orientation of the unique principal axis (C–D bond) with respect to the external magnetic field. This means that different parts of the sample relax with different rates. Fortunately, in general, this effect is small and the powder average T_1 often describes the relaxation process in the crystal satisfactorily.¹¹

For the spin-lattice relaxation of ^2H the dependence of T_1 on the correlation time is given by

$$\frac{1}{T_1} = C \left\{ \frac{\tau_c}{1 + \omega_o^2 \tau_c^2} + \frac{4\tau_c}{1 + 4\omega_o^2 \tau_c^2} \right\} \quad (1)$$

Two regions occur depending on the magnitude of the correlation time. On the low temperature side of the T_1 minimum the rate of the molecular motion is slower than at the minimum, i.e., $\omega_o \tau_c \gg 1$. Combining equation (1) with the Arrhenius equation, it can be seen that the natural logarithm of the spin-lattice relaxation time depends on inverse temperature

$$\ln(T_1) = \frac{E_a}{RT} + \ln \left\{ \frac{\omega_o^2 A}{2C} \right\} \quad (2)$$

On the high temperature side of the minimum the motion is faster than at the minimum, i.e., $\omega_o \tau_c \ll 1$

$$\ln(T_1) = \frac{E_a}{RT} - \ln(5CA) \quad (3)$$

Thus in both cases the Arrhenius activation energy (E_a) can be obtained from the slope of a plot of $\ln(T_1)$ vs $1/T$.

In certain cases, however, there is also a dependence of T_1 upon the amplitude of the motion. In these cases the parameter E_a is called the apparent activation energy.

4 MAXIMUM DIPOLAR BROADENING

In high resolution CP/MAS NMR, ^1H dipolar decoupling is extensively used to remove any remaining dipolar and J coupling from ^1H to heteronuclei. Invariably this is done by a single frequency placed near the centre of the ^1H resonance. Typical values for the dipolar decoupling field are in the region 50–100 kHz. If there is a molecular motion or exchange taking place at or near this frequency it can interfere with the efficiency of the decoupling and this causes an increase in the line widths of the affected resonances. This effect was first noted by Rothwell and Waugh.¹² In effect the frequency of the incoherent molecular motion is interfering with the coherent decoupling field reducing its efficiency and broadening the line. Maximum dipolar broadening is most often observed as an increase followed by a reduction in line width as the

Figure 4 The sigmatropic rearrangement and rotational processes in solid bullvalene that give rise to the dynamic spectral changes seen in Figure 5. Reproduced with permission from Figure 1 in Ref.⁶

Figure 5 75.47 MHz ^{13}C CP/MAS spectra at variable temperature arising from the dynamic processes inside solid bullvalene illustrated in Figure 4. Reproduced with permission from Figure 2 in Ref.⁶

temperature is varied. A single rate constant at the temperature of maximum broadening may be extracted in the region $5\text{--}10 \times 10^4 \text{ s}^{-1}$.

An example of the use of maximum dynamic broadening may be found in work by Twyman and Dobson.¹³ They showed that a combination of line shape analysis, maximum dipolar broadening and magnetization transfer could be used to study the phenyl rotation in the compounds (3) and (4) over a wide range of rates of rotation.

5 $T_{1\rho}$ MEASUREMENTS

Maximum dynamic broadening is, however, generally not the best way to study molecular motions in this frequency range in CP/MAS spectra. Measurements of $T_{1\rho}$ are generally superior.¹⁴ In the $T_{1\rho}$ experiment the magnetization to be studied is flipped from equilibrium through 90° to take the magnetization into the $x'y'$ plane, where it is spin locked along a particular axis.¹⁵ Thus a $90^\circ + x'$ pulse placing the magnetization onto the $+y'$ axis would be followed by a spin lock field (ω_1) (ca. 50–100 kHz) being applied along the y' axis. The time course of the decay of the spin locked magnetization gives the relaxation rate in the rotating frame with time constant $T_{1\rho}$. In general the 90° pulse would be applied by a cross polarization sequence in which the ^1H and X nucleus fields are matched. The same fields would be used for spin locking (X) and for decoupling (^1H). This makes the $T_{1\rho}$ method sensitive in the same region as maximum dipolar broadening.

In principle the spin lock frequency can be varied to probe different rates of molecular motion. In practice dynamic information is more readily obtained by following the variation of $T_{1\rho}$ with temperature than by varying the spin lock field.

^{13}C $T_{1\rho}$ can be modulated both by molecular motions and by the ^1H spin diffusion process

$$\frac{1}{^{13}\text{C } T_{1\rho}} = \frac{1}{^{13}\text{C } T_{1\rho \text{ spin lattice}}} + \frac{1}{T_{\text{CH}}(\text{ADRF})} \quad (4)$$

Figure 6 The ultrafast hydrogen bond exchanges in dimethyldibenzotetraaza[14]annulene studied by ^{15}N T_1 relaxation methods

^{13}C $T_{1\rho}$ spin lattice arises from modulation of the spin locking field by the molecular motion. $T_{\text{CH}}(\text{ADRF})$ comes from modulation of the dipolar interaction by the spontaneous rigid lattice proton fluctuations (spin diffusion). In practice the latter effects are generally found to be negligible with spin locking fields in excess of ca. 35 kHz. Also in practice $T_{1\rho}$ measurements in CP/MAS NMR are generally made with spin lock fields that are the same as those used for cross polarization and are 50 kHz or greater.

For a dipolar interaction between two unlike spins, e.g., ^{13}C and ^1H

$$\frac{1}{T_{1\rho}} = \frac{B^2\tau}{(1 + \omega_1^2\tau^2)} \quad (5)$$

where ω_1 is the frequency of ^{13}C in the spin lock field, τ is the rotational correlation time for the molecular motion causing the relaxation (rotational correlation time), and B^2 is a measure of the ^{13}C – ^1H dipolar interaction.¹⁶ B^2 may be calculated for a particular model of motion and geometry from the equation given by Abragam.¹⁷ The rate of the molecular motion will vary with temperature T and therefore $T_{1\rho}$ will have a temperature dependence. Equation (5) predicts that $T_{1\rho}$ will have a minimum at the temperature at which $\omega_1\tau = 1$.

Hence at the minimum value of $T_{1\rho}$, $\omega_1\tau = 1$ and B^2 conforms to

$$B^2 = \frac{2}{(T_{1\rho})_{\min}\tau} \quad (6)$$

Thus the minimum value of $T_{1\rho}$ allows an experimental determination of B^2 . Two things follow from this. First the values of τ at each temperature may be extracted by solving the appropriate quadratic equation. Secondly the mode of motion may be checked by comparison of the calculated and experimental values of B^2 .¹⁸

The use and validity of $T_{1\rho}$ methods is illustrated in a study of the rotation of both *tert*-butyl groups in (5). Line shape analysis in the temperature range 202–233 K and $T_{1\rho}$ measurements in the temperature range 224–320 K were carried out.

If the reductions in ^{13}C $T_{1\rho}$ in the *tert*-butyl groups arise from group rotations then four predictions can be made.

- Both the central and the methyl carbons in the same *tert*-butyl group should show $T_{1\rho}$ minima at the same temperature.
- For a constant geometry of *tert*-butyl groups the $T_{1\rho}$ minima should be the same for both groups.

Figure 7 Observed (a) and calculated (b) 76.773 MHz ^2H quadrupole echo spectrum of 1,1,6,6- d_4 -hexane-1,6-diyl bis(*p*-nitrobenzoate) at varying temperatures. The changes arise from librational motions of the CD_2 groups. Refocusing delays are 20 (a) and 120 μs (b). Reproduced with permission from Figure 6 in Ref.²⁰

- Rate constants determined from the $T_{1\rho}$ data and the line shape analyses should fall on the same Eyring or Arrhenius plots.
- Experimentally determined B^2 values for the methyl and quaternary carbons should agree with those derived from calculation.

All four predictions are found to be correct.¹⁶

The same group went on to examine a wide variety of molecular motions in crystalline organic compounds including the related rotations of trimethylammonium and trimethylphosphonium groups. Interestingly and satisfyingly for the trimethylphosphonium group the data from the ^{13}C line shape changes, the ^{13}C $T_{1\rho}$ data and the ^{31}P $T_{1\rho}$ data all fitted the same activation plot.¹⁹

One further important point about $T_{1\rho}$ methods is that the measure of the dipolar interaction B^2 depends upon the geometry of the molecular motion.¹⁷ In principle this allows differentiation between alternative models for the molecular motion. For example, in *trans*-1,2-cyclopentanediol this method allowed a differentiation to be made between a whole molecule rotation process and an internal ring pseudorotation process with the latter process being the more likely origin of the experimental measurements.¹⁸

6 ^2H QUADRUPOLE ECHO METHODS

^2H quadrupole echo line shape studies have been perhaps the widest used NMR technique for studying molecular motions in solids. Although ^2H incorporation in the molecule is required the technique has the compensation that information about both the frequency and geometry of the molecular motion can be obtained. Typically ^2H spectra of solids are a few hundred kilohertz wide. In the absence of molecular motions the spectrum is a Pake

doublet with the horns of the pattern separated by the quadrupolar coupling constant. For a C–D bond this is ca. 125 kHz. As the frequencies of the molecular motions approach the value of the quadrupolar coupling constant the line shape changes. Figure 7 shows typical changes in the quadrupole echo spectra for 1,1,6,6- d_4 -hexane-1,6-diyl bis(*p*-nitrobenzoate) (**6**).²⁰ The line shape depends upon the motion of the C–D bond and can be calculated on the basis of frequency of the molecular motion and various possible geometric modes that are possible.²¹ Conclusions can then be drawn.

With line shapes of this width the free induction delays can be very short and some or all of the FID can be lost in the receiver dead time delay. This would lead to weak and distorted signals. To overcome this the quadrupole echo sequence is used in which a second $\pi/2$ pulse is applied in quadrature with the first at time τ . This results in refocussing of the magnetization and the formation of an echo at approximately 2τ after the first pulse.²² By starting the FT at the echo maximum one does not need to worry about signal that has been lost during the receiver dead time and undistorted spectra may be obtained.

An additional complication is that artifacts can be caused by the finite length of the $\pi/2$ pulse width. This can lead to uneven excitation of the spectrum, to a feed through signal or to a virtual FID. Fortunately the program MXET1 that is most often used for the simulation of 2H quadrupolar echo spectra includes a correction factor for the $\pi/2$ pulse width meaning that correct spectra can be calculated.²³

Finally, for a more certain assignment between different models of motion it is important that spectra are measured with different refocusing delays for comparison with simulated spectra. With longer delays more spectral intensity is lost and the measurement of quadrupole echo spectra in the intermediate exchange regime can become very time consuming for long refocusing delays since the echo intensity decays exponentially with the refocusing delay. In addition to the motional effects (T_2) in the intermediate exchange region the echo intensity is also decreased by dipolar couplings between deuterons and protons as the quadrupole echo sequence fails to refocus these couplings. Dipolar couplings also broaden the line shape and their effect can be taken into account by multiplying the free induction decay by a Gaussian broadening function that is a few kilohertz wide. Such a broadening has a fairly small effect on the line shape but the decrease in the echo intensity during the refocusing delay is considerable. For refocusing delays of 20 μ s and 160 μ s and an effective 2 kHz broadening it can be shown that the effect is an echo reduction of 0.67, and for an effective 3 kHz broadening the corresponding reduction would be 0.40. Thus, dipolar couplings reduce the echo intensity to about half its original intensity in addition to the T_2 effects in the intermediate exchange region. Thus for delays of 20 μ s and 160 μ s an echo reduction factor of ca. 0.5 is expected. If the echo reduction factor falls below this it is indicative of T_2 effects becoming important during the refocusing delay. If the echo reduction factor is greater than this it seems likely that the dipolar couplings between deuterons and protons are becoming less important. Either way an additional pointer is given to assist interpretation.²⁴ Figure 7 shows the effect of the echo reduction factor in the quadrupole echo spectra of 1,1,6,6-d₄-hexane-1,6-diyl bis(*p*-nitrobenzoate) (6).

The angle of the C–D bond motion can be measured directly from a two-dimensional deuterium exchange experiment.²⁵ In the absence of molecular motion the 2D exchange spectrum consists of a Pake doublet along the diagonal. Molecular motions in the slow exchange regime where the correlation time is longer than a millisecond induce intensity off the diagonal. These off-diagonal ridges are very characteristic to motional modes and also in favourable cases allow direct measurements of the angle of the C–D bond motion to be made. Slowly moving deuterons, however, tend to relax very slowly and so in the absence of any additional relaxation modes these long relaxation times can make this technique very time-consuming.

7 MEASUREMENT OF TEMPERATURE IN MAS EXPERIMENTS

The establishment of temperatures in MAS NMR experiments is an important but difficult problem.²⁶ It is important

because accurate temperatures are needed if activation parameters are to be determined for a particular process. It is difficult because it has been demonstrated by several groups that MAS causes the sample to heat. This heating is probably due to friction. It has been proposed and demonstrated that the heating varies with the square of the spinning speed.^{26,27} Thus, at high spinning speeds careful temperature calibration becomes even more important. Several methods have been proposed for the measurement of sample temperatures. Probably the most reliable is to follow accurately known phase changes that show changes in the spectra through the transition.²⁶ Using this method it is possible to reliably calibrate a probe/temperature controller combination.

The use of NMR spectroscopy as a tool for the study of the dynamics of hydrogen and deuterium transfer in liquids and solids is demonstrated using a number of examples. (1) Single H Transfer dynamics in weak Hydrogen bonds. Example: Kinetic H/D/T isotope effects on the tautomerism of the porphyrin anion in the liquid and the solid state studied by NMR lineshape analysis. (2) Ultrafast Hydrogen Transfer in Hydrogen bonds of medium strength. Example: Solid tetraazaannulene, studied using ^{15}N CPMAS NMR relaxometry. (3) Triple Proton Transfer in solid Dimethylpyrazole: An example of determination of multiple kinetic isotope effects by ^{15}N CMAS lineshape analysis and magnetization transfer experiments.

1 INTRODUCTION

Hydrogen Transfer and Bonding are important phenomena in biophysical chemistry.¹ Whereas theoretical and laser chemistry have allowed us a deep understanding of these phenomena in the case of isolated molecules and molecular systems our knowledge referring to the liquid state where the majority of chemical and biochemical reactions takes place is much less advanced. This is mainly because different hydrogen bonded species, different local environments and molecular conformations often lead to a lack of resolution in optical and vibrational spectroscopy. On the other hand, high resolution NMR spectroscopy as a 'slow' method sees a molecule in solution as a single entity, where the different environments are averaged out by fast molecular translational and rotational diffusion. Nevertheless, NMR has been always used as a tool for the study of hydrogen bond phenomena, in spite of its limitations. However, many NMR spectroscopists have not yet realized the progress of NMR made in this field in the past decades, which was induced by the general improvement of NMR such as high resolution and dipolar solid state NMR, solid state

NMR-relaxation or low-temperature liquid state NMR techniques.

The purpose of this article is, therefore, to review these recent developments using simple introductory examples which are self-explanatory for the NMR-spectroscopists. These examples are taken from my work in the past years. Thus, no attempt is made to give a comprehensive description but rather to give an overall impression of the number of phenomena studied.

One general comment concerning the nomenclature. By NMR we observe either the moving nuclei, i.e., protons, deuterons, tritons which are generally called 'hydrons', or nuclei to which these particles are attached. In the nomenclature of chemistry, hydrons are, however, always bound to heavy atoms, i.e., they do not exist as isolated particles. Therefore, we will often use the term 'hydrogen transfer' instead of proton transfer, if we can not decide whether only a hydron changes place or whether also electrons are moving at the same time which compensate the charge of the proton. We will use the term 'proton transfer' mainly if it is clear that a proton is transferred with its positive charge.

We will start with single and multiple hydrogen transfer processes between nitrogen involving a barrier that will be gradually removed as the N-H...N hydrogen bond strength is increased. The techniques of line shape analysis, magnetization transfer and longitudinal relaxation are used in order to follow the hydrogen transfer kinetics. Generally, we will exploit the modulation of isotropic chemical shifts associated with the hydrogen transfer, a stratagem which works in the case of liquids and solids, where high-resolution NMR spectroscopy under the conditions of magic angle spinning (MAS) and cross polarization (CP) can be employed.² In the case of liquids and hydrogen transfer from and to nitrogen, however, also the modulation of scalar ^1H - ^{15}N coupling during hydrogen transfer is a very useful phenomenon to exploit.

2 SINGLE H/D/T TRANSFER ALONG WEAK HYDROGEN BONDS

2.1 Example: The Conjugate Porphyrin Anion

In this section we will discuss the elucidation of the kinetics of the tautomerism of the conjugate ^{15}N -labeled porphyrin anion (Por-H⁻), a process reported by Braun et al.^{3,4} which is depicted Figure 1. The anion was prepared by abstraction of a proton from the ^{15}N -labeled parent compound porphyrin (Por-H₂) by the phosphazene base P₄ (Figure 1). The rate constants of the proton transfer k^{H} in the conjugate porphyrin anion were determined by analysis of the variable temperature NMR signals of the inner proton of in Por-H⁻ dissolved in THF-*d*₈ as depicted in Figure 1(a). The signals appear around -2.7 ppm which is typical for porphyrins; for comparison, the corresponding signals of the parent compound appear at -3.5 ppm.⁵ At low temperatures, a doublet is observed arising from scalar coupling with the attached ^{15}N nucleus, indicating a slow exchange of the proton between the nitrogen sites. A differential line broadening of the ^1H - ^{15}N doublet is observed at low temperature and arises from a reduced molecular mobility and an interference between the ^1H - ^{15}N dipolar interaction and the chemical shift anisotropy.⁶ As temperature is increased, rotational diffusion becomes faster and the asymmetry disappears.

Figure 1 Superposed experimental and calculated variable temperature high field NMR signals of the inner hydrons of the ^{15}N -labeled conjugate porphyrin anion, with the protonated P4-phosphacene base as counteranion. Adapted from Braun et al.⁴ (a) ^1H NMR of a sample containing 65% Por-H⁻ and 35% Por-D⁻ dissolved in THF- d_8 . Concentration app. 0.015 M; 500 MHz, 65° pulses, duration 6.5 μs , 9 KHz spectral width, 3.5 s repetition time, up to 600 scans. (b) ^3H NMR of a sample containing 10% Por-T⁻ dissolved in THF- h_8 ; 320 MHz, 5 μs 60° pulses, 8 KHz spectral width, 3.6 s repetition time, number of scans between 200 and 1400 below 250 K and up to 10 000 above 290 K

At the same time, a doublet-pentet transition is observed at about 200 K arising from a fast intramolecular proton transfer between all four nitrogen atoms. The observation of the pentet is proof for an intramolecular reaction pathway of the tautomerism. The rate constants k^{H} determined by adapting the computed spectra to the experimental spectra corresponds to the inverse average life-time of the proton in a given nitrogen site until either a clockwise or counterclockwise jump to an adjacent nitrogen site occurs, characterized by equal probabilities. No evidence for direct jumps to opposite nitrogen sites were obtained by line-shape analysis as such a process would induce a change of the inner proton signal from a doublet at low to a triplet at a higher temperature. In order to obtain k^{H} by line-shape analysis the value of the line-width W_0 in the absence of exchange is needed. This quantity can be derived at higher temperatures from the line-width of the outer signal components. At low temperatures, where only an exchange broadened doublet is observed, this procedure is not practicable. Here, the signals were simulated by simulating the carbon bound proton signals from which after partial deuteration, also the rate constants k^{D} are obtained.⁴

In a similar way, the NMR signals of the inner triton of (Por-T⁻) were measured and analyzed by ^3H NMR, and the rate constants k^{T} of the triton transfer determined, as indicated in Figure 1(b). The doublet-pentet transition temperature is substantially higher for the triton as compared to the proton, indicating a large kinetic H/T isotope effect on the tautomerism.

In order to know the influence of possible cation-anion or other interactions on the tautomerism, variable temperature ^{15}N CPMAS NMR experiments at 9.12 MHz were performed on [Por-H]⁻ embedded into the phosphacene fluoride depicted in Figure 2. Due to the small magnetic field applied, spinning speeds of between 1.9 KHz and 2.2 KHz were sufficient to suppress the rotational sidebands. At low temperatures, three singlets are observed, exhibiting a ratio of app. 1:2:1. The assignment is straightforward: the high-field line arises from the protonated nitrogen, the low-field line from the opposite nitrogen, and the remaining line from the two lateral chemically equivalent nitrogen atoms. As temperature is increased, all lines broaden and coalesce indicating a rapid tautomerism also in the solid state. Moreover, at high temperatures only one single line is observed indicating that the tautomerism renders all nitrogen atoms equivalent. In other words, the gas phase and liquid state degeneracy of the tautomerism is not lifted in the solid matrix. This result is not trivial; although it was also found for the parent compound porphyrin:⁵ in most substituted porphyrins the symmetry is lifted by the crystal field.⁷

The line-shape analysis of Figure 2 was carried out in the usual way by setting up the appropriate line-shape equations of intramolecular exchange. The line-width in the absence of exchange were taken from the spectrum at 109 K and the chemical shifts kept constant within the whole temperature range.

The Arrhenius diagram obtained is depicted in Figure 3. Within the margin of error, the rate constants of the proton

Figure 2 Superposed experimental and calculated variable temperature ^{15}N CPMAS NMR spectra of Por-H^- embedded in solid P_5^+F^- . 9.12 MHz, 3 to 9 ms CP times, 7 KHz spectral width, 3.3 s repetition time, 1.9–2.2 KHz spinning speed. Flame-sealed glass insert in a 7 mm rotor. The peak labeled with an asterisk arises from an impurity formed during flame sealing. (Adapted from Braun et al.⁴)

tautomerism are identical in the liquid and the solid. This means, that in first order the porphyrin skeleton shields the reaction center from the surroundings. The Arrhenius curves of the corresponding processes in the parent compound⁵ are also included. We note that especially the proton tautomerism becomes much faster by removing one proton from porphyrin whereas the effect on the D- and the T-transfers are less pronounced. Moreover, the temperature dependence of the rate constants does not follow the Arrhenius law. Together with the large size of the kinetic H/D/T-isotope effects these results indicate a proton tunneling mechanism. This finding is reproduced in terms of a modified Bell⁸ tunnel model for both systems.⁴ For the parent porphyrin, the tautomerism is stepwise and the transfer of the first proton leads to a metastable intermediate (Figure 3). Proton tunneling cannot occur below the energy of this intermediate. By contrast, in the anion the single proton transfer is degenerate, and tunneling can occur at lower energies. As this phenomenon is very dependent on the mass, it follows that the H-transfer in the anion is especially accelerated as compared to the D- and the T-transfer.

Vangberg et al. have performed ab initio calculations on the tautomerism of the anion.⁹ This surface was used by Brackhagen et al.¹⁰ in order to formulate a quantum-mechanical

description of the H/D/T-tautomerism. By adapting the calculated set of rate constants to the experimental one insight into the details of the tautomerism could be obtained. This example shows already how dynamic NMR can provide kinetic data which can be used in order to calibrate quantum-mechanical reaction models in polyatomic molecules in condensed phases.

3 MICRO- AND NANOSECOND HYDROGEN TRANSFER PROCESSES IN HYDROGEN BONDS OF MEDIUM STRENGTH

3.1 Example: Tetraazaannulenes

Whereas in the previous section rate constants were obtained by line shape analysis in the millisecond time scale, the relaxation method allows us to obtain rate constants of proton transfer in solids in the micro- to nanosecond timescale. This method can be used for solids where normal rotational diffusion as a source of relaxation is suppressed. The reason is that the dipolar interactions between moving and non-moving protons are modulated leading to an important source of relaxation in the solid state.^{11,12} On the other hand, moving deuterons lead to a modulation of the quadrupole interaction

Figure 3 Arrhenius diagram of the H, D, and T transfer in the conjugate porphyrin anion evaluated by dynamic NMR. For comparison, the Arrhenius curves of the parent porphyrin Por-H₂ are included. (Adapted from Braun et al.⁴)

and hence to quadrupole relaxation.¹³ In order to obtain rate constants of the proton motion it is necessary to know the equilibrium constants. The latter can be obtained in the case of ²H NMR studies but not easily by ¹H NMR. Also, the study of polycrystalline powders is difficult.

Finally, we note that the problem can also be overcome by ¹H relaxation as a function of the strength of the magnetic field, a method advanced by Horsewill et al.¹²

In the case of proton transfer from and to nitrogen, ¹⁵N CPMAS can provide the equilibrium constants in a simple way. By combination with ¹⁵N relaxation measurements under CPMAS conditions it is then possible to obtain also the rate constants.

3.2 Dimethyltetraaza[14]annulene (DTAA)

First we will treat the tautomerism of the tetraazaannulene derivative DTAA – discovered by Limbach et al.¹⁴ Hoelger et al.¹⁵ have used this molecule in order to establish the method of ¹⁵N longitudinal relaxation under CPMAS conditions and to link it to the technique of line shape analysis, as shown in the following.

In Figure 4(a) are depicted the variable-temperature ¹⁵N CPMAS spectra of ¹⁵N labeled DTAA. At low temperatures two lines are observed, the high-field line for the protonated and the low-field line for the non-protonated nitrogen. As temperature is increased the lines broaden, but do not coalesce. This situation is typical for an asymmetric situation, where the equilibrium constant of the tautomerism $K = k_{12}/k_{21} = x_1/x_2 < 1$ in the whole temperature range, where k_{12} represents the forward reaction rate constant and x_1 the mole fraction of state **1**, with $x_1 + x_2 = 1$. This leads at high temperatures to two different nitrogen atoms **a** and **b**, where **a** experiences a higher average proton density as compared to **b**. Hence, the chemical shift of **a** at high temperatures is given by

$$\nu_a = x_1 \nu_{a1} + x_2 \nu_{a2} = \frac{\nu_{a1} + K \nu_{a2}}{1 + K} \quad (1)$$

where ν_{a1} represents the chemical shift of nucleus **a** in tautomeric state **1**. A similar equation is valid for ν_b from

which it follows, that the chemical shift difference at high temperature is given by

$$\delta \nu_{ab} = \nu_a - \nu_b = \Delta \nu_{ab} \frac{1 - K}{1 + K}, \Delta \nu = \nu_N - \nu_{NH} \quad (2)$$

From equation (2) it is easy to obtain the equilibrium constant at high temperatures by comparison of the high and the low-temperature line splittings $\delta \nu_{ab}$ and $\Delta \nu_{ab}$. Once K is obtained at different temperatures it can be extrapolated using the van't Hoff equation to lower temperatures. Then, by line shape analysis rate constants k_{12} can be obtained as indicated in Figure 4(a).

Because of the limited dynamic range the longitudinal ¹⁵N relaxation times of ¹⁵N labeled DTAA were measured under MAS conditions at 2.1 and 7 Tesla,¹⁵ as indicated in Figure 4(b). For this purpose, the usual sequence of Torchia¹⁶ in connection with CP was employed. A T_1 – minimum was observed around 350 K and 2.1 Tesla. Deuteration of the compound increased the T_1 values strongly, providing evidence that relaxation is caused by the proton jumps that modulate the heteronuclear ¹H-¹⁵N dipolar coupling. Starting from the homonuclear ¹H relaxation theory in the presence of solid state proton transfer¹¹ equations for the heteronuclear case were derived. It was shown that both nitrogen atoms **a** and **b** of a N_a-H- -N_b exhibit the same relaxation times. The latter are normally strongly dependent in the case of a static sample on the orientation of the crystallite with respect to the magnetic field. However, MAS averages out these differences and the relaxation times measured under MAS conditions are almost identical with the isotropic values, which one would obtain for the case of an isotropic rotational diffusion when the latter is not active for relaxation. The final equation used for the data analysis of Figure 4(b) is given by

$$\frac{1}{T_1} = \frac{1}{40} \gamma_N^2 \gamma_H^2 \left(\frac{h}{2\pi} \right)^2 \left(\frac{\mu_0}{4\pi} \right)^2 D \left[\frac{4K}{(1+K)^2} \right] \times \left[\frac{\tau_c}{1 + (\omega_H - \omega_N)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_N^2 \tau_c^2} + \frac{6\tau_c}{1 + (\omega_H + \omega_N)^2 \tau_c^2} \right] \quad (3)$$

Figure 4 (a) Superposed experimental and theoretical ^{15}N CPMAS NMR spectra of crystalline DTAA. (b) ^{15}N - T_1 analysis. (c) Arrhenius diagram. (Adapted from Hoelger et al.¹⁵)

τ_c is the correlation time of the proton motion whose temperature dependence may be expressed in a first approximation by the Arrhenius equation

$$\frac{1}{\tau_c} = k_{12} + k_{21}, k_{12} = A_{12} \exp\left(\frac{-E_{a12}}{RT}\right) \quad (4)$$

where E_{a12} is the energy of activation of the forward reaction and A_{12} the corresponding frequency factor. The factor D represents the change of the dipolar interaction during the proton jump

$$D = r_1^{-6} + r_2^{-6} + r_1^{-3}r_2^{-3}(1 - 3\cos^2\theta^d) \quad (5)$$

r_1 represents – for a given nitrogen atom – the short NH distance before and r_2 the long $\text{N} \cdots \text{H}$ distance after the proton has jumped. θ^d represents the angle between the NH vectors before and after the proton transfer, ω represents a Larmor frequency and γ a gyromagnetic ratio.

Using equation (4), the solid lines in Figure 5(b) were calculated using a non-linear least-squares fitting routine,

by adapting D – characterizing the T_1 value in the minimum, A_{12} and E_{a12} and assuming an Arrhenius law for the tautomerism. From the value of D it is possible to obtain an approximation of the cubic average short NH-distance $r_1 \equiv r_{\text{NH}} = 1.03 \text{ \AA}$ which coincides within the margin of error with the value obtained by dipolar NMR for the deuterated compound.¹⁷ Using the parameter set obtained, the relaxation data at 7 Tesla included in Figure 4(b) could be calculated. However, the calculated values were slightly longer than the experimental ones, indicating that at 7 Tesla relaxation via the modulation of the Chemical Shielding Anisotropy by the jumping protons is no longer negligible. Thus, this technique is preferentially performed at lower magnetic fields.

In a second stage of the analysis the assumption of an Arrhenius-law for the proton motion was dropped, and each ^{15}N T_1 value obtained at 2.1 Tesla separately converted into the rate constant k_{12} of the forward proton transfer. The values are plotted together with those obtained by line shape analysis in the Arrhenius diagram of Figure 4(c). The two methods are nearly overlapping, and provide in the overlapping range

Figure 5 Results of the NMR-experiments on solid TTAA according to Langer et al.²¹ (a) The solid state tautomerism of TTAA. (b) Crystal structure of TTAA according to Goedken et al.¹⁹ (c) Geometries of the two intramolecular hydrogen bonds in TTAA, adapted from the crystal structure assuming a planar arrangement. The two positions of each proton are indicated, the angle θ^d is the jump angle of the dipolar $^1\text{H}-^{15}\text{N}$ interaction, and α the hydrogen bond angle. θ^q represents the corresponding jump angle of the quadrupole interaction. (d) 9.12 MHz ^{15}N CPMAS-NMR spectra of 95% ^{15}N enriched TTAA at 9.12 MHz as a function of temperature; 6–10 ms cross-polarization time, 7 KHz spectral width, 2.7 s repetition time, 100 scans on average, 2–2.8 KHz rotation frequency (adapted from Wehrle et al.²²). (e) Temperature dependence of the spin diffusion averaged ^{15}N T_1 relaxation time of polycrystalline TTAA at 9.12 MHz. The solid line was calculated according to equation (3) using the fixed ratios $A_{31}/A_{13} = 1.31$ and $A_{32}/A_{23} = 1.66$ derived in equation (17) and parameter fit of $A_{13} = 1.6 \times 10^{12} \text{ s}^{-1}$, $E_{23} = 14 \text{ KJ mol}^{-1}$, $E_{31} = 41 \text{ KJ mol}^{-1}$, and the NH-bond length 1.04 Å. The dashed lines correspond to the intrinsic relaxation times of the nitrogen pairs Na/Nb and Nc/Nd. The T_1 values of the two nitrogen atoms in each pair are identical. (f) T_1 values of deuterons b and e in TTAA plotted in a logarithmic scale as a function of the inverse temperature. (g) Arrhenius diagram of the relaxation active proton and deuteron transfer step $3 \rightleftharpoons 2$ of the solid state tautomerism of TTAA. The solid lines were calculated using a modified Bell tunneling model. (h) Energy profile for the double proton transfer in TTAA

similar rate constants which establishes the ^{15}N relaxation method as an important kinetic tool. Rate constants are obtained until the nanosecond time scale. A slight deviation from an Arrhenius behavior is observed, which is, however, less pronounced as in the case of porphyrin and its conjugated anion. This effect was explained again in terms of a stepwise proton motion, where the *cis*-intermediate exhibits, however, such a high energy that tunneling is not operative.

Finally, we note that the relaxation method discussed here has been recently used in order to obtain the rate constants of the proton motion in the solid porphyrin analog porphycene.¹⁸

3.3 Tetramethyltetraaza[14]annulene (TTAA)

As an example of the determination of kinetic H/D-isotope effects on the tautomerism we discuss in the following the related TTAA molecule (Figure 5a). Its crystallographic structure is shown in Figure 5(b),¹⁹ and a simplified hydrogen bond structure needed for the interpretation of the relaxation experiments described below in Figure 5(c). The solid state tautomerism of this compound was discovered by Limbach et al.²⁰ The following results are taken from a recent paper of Langer et al.²¹

The ^{15}N CPMAS spectra of the polycrystalline powder obtained at 2.1 Tesla exhibit four sharp lines a, c, d, and f in the whole temperature range between 86 and 405 K, as depicted in Figure 5(d), with the line separations $\delta_{ac} = \delta_a - \delta_c$ and $\delta_{df} = \delta_d - \delta_f$. This result indicated four chemically inequivalent nitrogen atoms exhibiting different temperature-dependent proton densities. By performing so-called ‘spin diffusion’ experiments discussed in a later section it was shown that each molecule in the asymmetric unit contains all types of nitrogen atoms. This result is then only consistent with the presence of more than two tautomeric states, i.e., with a stepwise proton transfer mechanism. In other words, in contrast to DTAA, the energy of the *cis*-intermediate must be substantially lowered. Deuteration of the inner proton sites did not affect at all line positions. This means that there are no H/D-isotope effects on the proton transfer equilibria of solid TTAA. A careful analysis of the splittings δ_{ac} and δ_{df} in terms of the reaction network of Figure 5(a) showed that only states **1**, **2** and **3** are populated but not state **4**.²² Furthermore, the energy differences between the states could be obtained.

In order to analyze the ^{15}N T_1 values obtained at 9.12 MHz of Figure 5(e) as a function of temperature – which exhibited only a very small and puzzling temperature dependence – we needed to extend the ^{15}N relaxation theory to the two-step proton transfer $\mathbf{1} \rightleftharpoons \mathbf{3} \rightleftharpoons \mathbf{2}$ and to have an idea of the exact hydrogen bond geometry which was obtained in approximation as follows as no neutron diffraction study of TTAA was available. Knowing the array of the nitrogen atoms from the crystal structure, we assumed that the hydrogen atoms are located in the plane of this array, and that the short NH distances r_{NH} and the long NH-distances $r_{\text{H} \cdots \text{N}}$ distances are the same for all hydrogen bonds in all tautomers. First we set $r_{\text{NH}} = 1.03 \text{ \AA}$ which is within the margin of error identical with the value of $1.04 \text{ \AA}$ obtained by dipolar relaxometry and dipolar ND – coupling for the related DTAA molecule.¹⁷ The slightly smaller value was later justified by a least squares fit of the relaxation data.

Knowing the short N–H distance, we made use of the well-known correlation between r_{NH} and $r_{\text{H} \cdots \text{N}}$ of NHN–Hydrogen bonds established by neutron diffraction,²³ NMR and theoretical calculations,²⁴ from which we obtained a long N $\cdots$ H distance of $1.94 \text{ \AA}$. Taking into account the crystallographic distance of $r_{\text{NN}} = 2.675 \text{ \AA}$ between the two nitrogen atoms of a given hydrogen bond and of $r_{\text{NN}'} = 2.699 \text{ \AA}$ between closest nitrogen neighbors in different hydrogen bonds,¹⁹ we derived then the proton positions of Figure 5(c), exhibiting a hydrogen bond angle of $\alpha = 134^\circ$, a dipolar proton jump angle of $\theta^d = 13.7^\circ$, and a quadrupolar jump angle of $\theta^q = 104^\circ$.

With this parameter set, the individual T_1 values of all nitrogen atoms could be calculated, and hence the value of all nitrogen atoms, averaged by spin diffusion. The energy profile for this motion is depicted in Figure 5(h). The agreement between the calculated and experimental values is very satisfactory. The theory predicts two minima, one at low temperatures for the fast process $\mathbf{3} \rightleftharpoons \mathbf{2}$ and one at high temperatures, arising from the process $\mathbf{1} \rightleftharpoons \mathbf{3}$. As in the fast process only H_b is jumping between N_a and N_c , only these two atoms should experience a short relaxation time at low temperatures, but not N_d and N_e . However, spin diffusion averages this difference.

Independent evidence for this interpretation could be obtained by ^2H NMR relaxation time measurements of the static deuterium labeled solid, where the results are depicted in Figure 5(f). Effectively, two deuterons were observed at room temperature exhibiting different relaxation times, a short one (31 ms) attributed to D_b and a very long one (5.6 s) attributed to D_e .

In the final step, the ^{15}N T_1 values could be converted to the rate constants k_{32}^{H} and the ^2H T_1 to k_{32}^{D} . The Arrhenius diagram is depicted in Figure 5(g). As compared to DTAA, the process is much faster which we attributed to the more symmetric profile of the reaction, in a similar way as in the porphyrin anion case. Tunneling is pronounced as the Arrhenius curves exhibit a strong curvature. The kinetic H/D isotope effects are much smaller than in the porphyrin anion. These results may provide again input data for computational studies of this reaction.

Finally, we note that TTAA is not only interesting from the standpoint of theory but also from a practical view, as it provides a very convenient chemical shift thermometer for ^{15}N CPMAS measurements.²² Temperature control in MAS is very important as spinning can strongly increase temperature.²² An example of its use will be reported in a subsequent section.

3.4 The Tautomerism of TTAA in a Glassy Polystyrene Matrix

The observation that intermolecular interactions perturb the symmetry of a proton transfer system can be rationalized in the scenario of Figure 6. When a bistable molecule exhibiting a symmetric double well for the proton motion in the gas phase is placed in a molecular crystalline environment, the crystal field will induce an energy difference ΔE between the tautomers (Figure 6b), whereas ΔE will be the same for all molecules in a crystal and ΔE will depend in a disordered system such as a glass on the local environment, leading to a distribution of ΔE -values (Figure 6c). At the glass point, some environments may become mobile leading to an average value of $\Delta E_{\text{av}} = 0$, whereas other environments still experience non-zero values.

Figure 6 Model for the dependence of the proton transfer potential on the environment arising from experimental observations. (Adapted from Wehrle et al.²⁵)

Only well above the glass transition is a situation typical for the liquid reached where all molecules exhibit an average value $\Delta E_{av} = 0$ (Figure 6d).

In the case of N-H...N proton transfer systems the ^{15}N CPMAS line shape for the sequence of Figure 5 has been described, and experimentally verified using the example of TTAA dissolved in solid polystyrene.²⁵

3.5 Triple Proton Transfer in Solid Dimethylpyrazole: An Example of Determination of Multiple Kinetic Isotope Effects by ^{15}N CMAS Lineshape Analysis and Magnetization Transfer Experiments

In this section we will introduce three complications, i.e., the problem of the determination of kinetic isotope effects in multiple proton transfer reactions, the case of slow proton dynamics, and the use of the chemical shift thermometer TTAA. In previous liquid state NMR work, we have determined kinetic HH/HD/DD isotope effects of the double proton transfer between acetic acid and methanol already in 1984.²⁶ However, only in this year, has this process has been modeled a priori.²⁷ In addition, multiple kinetic isotope effects have been measured for diarylamidines,²⁸ which represent the nitrogen analogs of carboxylic acids. The solid state tautomerism of this class of compounds has been reported recently.²⁹ These studies are still underway. Therefore, as an example, we will treat here the triple proton transfer in solid 3,5-dimethylpyrazole (DMP) (Figure 7a), a process described by Elguero et al.³⁰ The following results are taken from the paper of Aguilar et al.³¹

The X-ray crystal structure (Figure 7b) shows that this molecule forms a cyclic trimer in the solid state, with half protons close to each nitrogen atom. X-ray diffraction can, however, not distinguish between a ‘dynamic disorder’ where each molecule can form both tautomeric states to a comparable extent and a ‘static disorder’ with alternate fixed proton positions from one molecule to the other. The ^{15}N CPMAS spectra of DMP and of its deuterated analog obtained at 7 Tesla with fast speed spinning in order to avoid spinning sidebands are depicted in Figure 7(c) and (d). At low temperatures, two signals are observed for the amino-(–NH–, –ND–) and imino-(–N=) nitrogen atom sites. The cross polarization times used in the experiments were adjusted in such a way that the signals of the amino and imino nitrogen atoms sites were equal. As temperature is increased, the lines broaden and coalesce.

As we know from the crystal structure that the molecule forms cyclic trimers, the dynamic process averaging the two isotropic ^{15}N chemical shifts can only correspond to a triple proton transfer. At high temperatures, only a single sharp line survives. This observation indicates that within the margin of error the transfer is degenerate. The coalescence temperature of the deuterated sample is much higher than for the protonated sample and is not reached at 7 Tesla within the temperature range where the compound is solid and indicates the presence of large primary isotope effect $k^{\text{HHH}}/k^{\text{DDD}}$ on the tautomerism. To the sample of Figure 7(c) a small amount of TTAA was added whose four lines (see Figure 5d) give information about the sample temperature. Thus, line shape analysis of the DMP signals using the usual two-site theory and simulation of the TTAA line positions give both the rate constants as well as the sample temperature, which is increased substantially as compared to the temperature of incoming nitrogen gas by fast MAS. Some rate constants k^{HHD} and k^{HDD} of the other isotopic reactions were obtained by ^{15}N CPMAS NMR line shape analyses of spectra obtained for partially deuterated samples at 2.1 Tesla.

Since at low temperatures the reaction rates are too small to be determined accurately enough by lineshape analysis, one-dimensional ^{15}N CPMAS magnetization transfer experiments in the laboratory frame between the amino nitrogen magnetization S and the imino nitrogen magnetization frame were performed at low temperatures, using a pulse sequence described previously.³² In these experiments S and X are created by cross polarization and stored by 90° pulses parallel to the magnetic field B_0 . The time dependence during this period is monitored after application of a second 90° pulse. The dependence is given by

$$S + X = (S_0 + X_0) \exp(-\rho t), \quad S - X = (S_0 - X_0) \exp\left(-\left(\frac{1}{T_1 + \sigma + 2k}\right)t\right) \quad (6)$$

where σ represents the rate of spin diffusion between S and X , and k the rate constant of the degenerate triple proton transfer. Two experiments are performed by setting a time interval t_1 between the spin lock pulses and the 90° pulse either to 0 or to $1/2(\nu_S - \nu_X)$, where ν_S and ν_X represent the chemical shifts in Hz of the exchanging sites. In the ‘parallel’ experiment (i) S_0 and X_0 have the same sign and are almost equal. Therefore $S - X = 0$ and S and X each decay with the longitudinal

relaxation rate ρ . In the ‘antiparallel’ experiment (ii) S_0 and X_0 are antiparallel, i.e., $S_0 \approx -X_0$, and each magnetization decays with $\rho + \sigma + 2k$ in time. As ρ is already known from experiment (i) the sum $\sigma + 2k$ is obtained in experiment (ii). Various stratagems have been proposed in order to obtain σ and k separately. Here we exploit the circumstance that σ is strongly dependent on the distance between the ^{15}N nuclei in contrast to k .

As the ^{15}N spin diffusion term σ in equation (6) depends on the internuclear ^{15}N distances, we minimized this term by performing experiments on singly ^{15}N labeled DMP, which reduced the decay constant $\sigma + 2k$ to $2k$ alone; a check by embedding singly ^{15}N labeled DMP into non-labeled DMP at 35% and 10% did not further reduce the observed decay rates.

In Figure 7(e) the results of a typical experiment at a deuterium fraction of $x_D = 0$ and 0.96, carried out at 30.41 MHz

and 131 K and spinning speeds of about 8 to 9 KHz i.e., in the regime of suppressed sidebands are depicted. No variation of the magnetizations within the time period covered is observed indicating that $1/T_1$ is so small that it can be neglected. In experiment (ii) performed on the same sample under otherwise similar conditions the two magnetizations cancel each other in the same time period because of the triple proton transfer. For comparison, the results of experiment (ii) on a sample with $x_D \approx 1$ are shown for comparison: no change of the magnetization is observed as the DDD process is very slow. The data analysis (Figure 7e bottom) indicates a mono-exponential from which k^{HHH} is obtained.

In Figure 7(f) are depicted the results of experiment (ii) performed at 210 K on two singly ^{15}N labeled DMP samples with $x_D = 0.2$ and 0.8 are compared. Assuming a statistical isotopic distribution, the ratio for the former sample is given

Figure 7 NMR results for the tautomerism of DMP according to Aguilar et al.³¹ (a) Triple proton transfer process monitored. (b) X-ray crystal structure of DMP according to Baldy et al.^{30a} (c) and (d) Superposed experimental and calculated 30.41 MHz (7 Tesla) ^{15}N CPMAS-NMR spectra of 95% ^{15}N enriched DMP at the deuterium fractions $x_D = 0$ (c) and $x_D = 1$ (d). Experimental conditions: 8–9 KHz sample spinning, 6–12 ms CP times, 4.3 s repetition time, $5\ \mu\text{s}$ ^1H 90° pulses. k^{HHH} and k^{DDD} are the rate constant of the triple proton and deuteron transfer. The four sharp lines with temperature dependent line positions stem from a small quantity of the chemical shift thermometer TTAA, added in a separate capsule inside the rotor. (e) 30.41 MHz ^{15}N CPMAS magnetization transfer experiment in the laboratory frame performed on a sample of singly ^{15}N labeled DMP at 131 K. From top to bottom: longitudinal T_1 experiment and magnetization transfer experiment at $x_D = 0$, and MT at $x_D = 0.99$, data analysis for $x_D = 0$. (f) Related experiment at 210 K with $x_D = 0.2$ and $x_D = 0.8$. For further information see text

Figure 8 Arrhenius diagram for the triple proton and deuteron transfer in solid DMP according to Aguilar-Parrilla et al.³¹

by $x_{\text{HHH}} : x_{\text{HHD}} : x_{\text{HDD}} : x_{\text{DDD}} = 0.512 : 0.384 : 0.096 : 0.08$ and in the second by $x_{\text{HHH}} : x_{\text{HHD}} : x_{\text{HDD}} : x_{\text{DDD}} = 0.008 : 0.096 : 0.384 : 0.512$. Thus, in the former mainly the HHH and the HHD, and in the latter the HDD and the DDD species dominate, leading to apparently bi-exponential decays in both cases; in the former case the fast and slow decay components are governed by $2k^{\text{HHH}}$ and $2k^{\text{HHD}}$, and in the second by $2k^{\text{HDD}}$ and $2k^{\text{DDD}}$. As a consequence the full kinetic HHH/HHD/HDD/DDD isotope effects of the triple proton transfer of DMP could be detected in a large temperature interval.

The Arrhenius diagram containing all the rate constant data for the proton and deuteron transfer in the different DMP species is depicted in Figure 8. Especially in the HHH and the HHD reaction, deviations from a classical Arrhenius behavior

were found. The solid lines were calculated in terms of a modified Bell tunneling model as mentioned already in the porphyrin anion case. The interpretation of the data is illustrated at the top of Figure 8. The kinetic data at high temperature indicate that the rule of the geometric mean (RGM) is fulfilled. This rule assumes that all values $k^{\text{HHH}}/k^{\text{HHD}} \approx k^{\text{HHD}}/k^{\text{HDD}} \approx k^{\text{HDD}}/k^{\text{DDD}}$ are equal.³¹ Such a case is expected for a concerted triple proton transfer mechanism where all protons loose zero-point energy in the transition state as illustrated in Figure 8. At lower temperatures deviations from the RGM indicate the presence of tunneling. Furthergoing experiments on pyrazole molecules exhibiting a variety of substituents of different size and electronic properties indicated that in the transition state the NHN-Hydrogen bonds are strongly compressed.³³

4 CONCLUSIONS

In this review, we have demonstrated the use of dynamic liquid and solid state NMR for the study of fast proton and deuteron transfer processes in heterocyclic compounds. The data obtained all indicate the importance of tunneling. They are important for the development of quantum theories of proton transfer and kinetic isotope effects in condensed matter. Techniques have been devised which allow us to use NMR as a tool for the study of proton transfer not only in the second- and millisecond timescale but also in the micro- to nanosecond timescale, if other molecular motions are suppressed as in the solid state.

Naturally, a challenging field opens up when the barrier of proton transfer is further reduced. Then, the realm of H/D isotope effects on hydrogen bond geometries, chemical shifts and coupling constants is reached that provides further details into the phenomenon of hydrogen bonding. This challenging field uses dipolar NMR spectroscopy²⁴ and low-temperature liquid state NMR techniques.³⁴ In this realm scalar couplings across hydrogen bonds provide new insight into this phenomenon, if it is possible to reach the slow hydrogen bond exchange regime in the liquid. This is naturally achieved by low temperature NMR methods that also provide information about the influence of the dielectric properties of the solvent on the hydrogen bond geometries. In addition, the technique of isotopic fractionation provides insights into the zero-point energy of hydrogen bonds. This field will be covered in another review that will appear elsewhere. The same is true for the rapidly expanding field of rotational tunnel splittings of hydrogen pairs in transition metal hydrides that give rise to interesting quantum exchange and tunneling phenomena.³⁵

1 INTRODUCTION

Most chemical species in solution do not possess a fixed structure but exist in some type of dynamic equilibrium. This may involve intramolecular exchange between identical or different configurations of the same compound or intermolecular exchange involving other chemical species. NMR spectroscopy is uniquely powerful for investigating both categories of dynamic process. This stems from the diversity of one- and two-dimensional NMR techniques and the wide magnitude range of their associated timescales.

1.1 Intramolecular Rearrangements

Molecules which undergo purely intramolecular rearrangements at rates which affect NMR lineshapes are described as stereochemically nonrigid. This terminology was proposed originally by Muetterties¹ and popularized by Cotton et al. from 1966 onwards. In 1968, Binsch² proposed that the study of the precise way in which NMR lineshapes are affected by chemical exchange be known as ‘dynamic NMR’ (DNMR) spectroscopy and he developed a general theoretical treatment for such lineshape changes in both first- and second-order spectra arising from single-site and multi-site exchanges.³ Total bandshape analysis has been very widely exploited and is discussed in depth elsewhere in this Encyclopedia (see *Chemical Exchange Effects on Spectra*). In 1975, an entire book⁴ was devoted to DNMR, and this still provides a recommended starting point for interested readers. More recent treatments of the theory are the monographs by Kaplan and Fraenkel,⁵ and Sandström.⁶ The reader is also referred to a number of reviews.^{7–10}

In cases where the intramolecular movement of atoms produces chemically distinguishable species the change is known as isomerization, but where the interconverting structures are chemically indistinguishable the term ‘fluxionality’ was proposed.^{11,12} The difference between these two cases is often debated, especially where the changes are largely configurational in nature. Whatever the circumstances, fluxional molecules are clearly a subset of nonrigid molecules. In this article, ‘fluxional motion’ will be interpreted somewhat more widely than its original definition to avoid an unnatural restriction in the discussion of stereochemical nonrigidity. The variety of intramolecular dynamic processes in inorganic and organometallic molecules is considerable, but the processes

Scheme 1

Scheme 2

can usefully be divided into those where atomic positions in a molecule are permuted without bond breaking and those which require the breaking and making of (different) bonds in the molecule.

These two different cases can be illustrated by the fluxionalities of pentacarbonyliron (Scheme 1) and η^1 -cyclopentadienyltrimethylsilicon (Scheme 2). In $\text{Fe}(\text{CO})_5$, interconversion between species involves only changes of C–Fe–C bond angles, but in the case of $\text{Me}_3\text{Si}(\eta^1\text{-C}_5\text{H}_5)$ there is a concerted breaking and making of Si–C bonds at each step. In less symmetrical examples of these rearrangements the interchanging species may not have totally indistinguishable structures, but the processes are still described as fluxional.

1.2 DNMR Methods and Timescales

The two fluxional organometallic species described above illustrate the strengths and weaknesses of DNMR spectroscopy. $[\text{Fe}(\text{CO})_5]$ is known to possess a trigonal bipyramidal structure, yet its ^{13}C NMR spectra measured at all accessible temperatures (down to -170°C) consist of a single line rather than two lines for the axial and equatorial CO environments, indicating that the fluxionality rapidly exchanges the ^{13}C shifts at rates too high to be measured at any temperature. In contrast, the breaking and making of Si–C bonds in $[\text{Me}_3\text{Si}(\eta^1\text{-C}_5\text{H}_5)]$ is slow on the ^1H NMR timescale at ambient temperatures and fast exchange is not achieved at the highest accessible temperatures before thermal decomposition sets in.¹³ Standard bandshape methods based on chemical shift and scalar coupling modulation can be used to measure rate processes typically in the range $1\text{--}10^4\text{ s}^{-1}$. However, this range can be extended in an upward direction, as required for compounds such as $[\text{Fe}(\text{CO})_5]$ or PF_5 , if other NMR parameters are used as probes of the rate processes. Such parameters are spin–lattice relaxation times either in the rotating frame ($T_{1\rho}$) or in the laboratory frame (T_1), the operative ranges of accessible rate constants now being $10^3\text{--}10^6\text{ s}^{-1}$ and $10^6\text{--}10^{10}\text{ s}^{-1}$, respectively. In contrast, the techniques of one-dimensional magnetization transfer^{14,15} and two-dimensional exchange spectroscopy (EXSY) (see *Two-Dimensional Methods of Monitoring Exchange*)¹⁶ enable much slower rate processes, in the approximate range $10^2\text{--}10^{-2}\text{ s}^{-1}$, to be measured with high accuracy. Thus, nowadays rate constants within a total range of $10^{-2}\text{--}10^{10}\text{ s}^{-1}$ may be determined by NMR methods. This corresponds to timescales, or nuclear site lifetimes, in the range $10^2\text{--}10^{-10}\text{ s}$, i.e. between hundreds of

seconds and picoseconds. Fortunately for chemists, this range embraces a wide variety of intramolecular fluxional rearrangements.

Activation energies of these fluxional processes, based on temperature dependences of rate constants, generally fall in the range 15–100 kJ mol⁻¹. Rate processes are preferably described in terms of the thermodynamic activation parameters $\Delta G^\ddagger$, $\Delta H^\ddagger$, and $\Delta S^\ddagger$ arising from the Eyring rate theory. The Gibbs function changes $\Delta G^\ddagger$ are least prone to systematic error⁶ and so this parameter, usually calculated for a temperature of 298.15 K, is chosen wherever possible for comparing energy barriers of different fluxional processes. The activation entropy $\Delta S^\ddagger$ is exceptionally difficult to measure with high precision. For purely intramolecular rearrangements of the type considered here, a value of around zero is expected unless there is a statistical contribution to the value arising from multiple pathways between exchanging structures.⁶

In this article a few seminal examples of fluxionality as studied by NMR techniques are used to illustrate the contribution of NMR to this area of structural chemistry. More detailed coverage may be found in more recent reviews.¹⁷

2 FLUXIONAL INORGANIC COMPOUNDS

The first report¹⁸ of fluxionality in inorganic chemistry was in 1955 when high-resolution NMR was in its infancy. In aluminum tris(tetrahydroborate) [Al(BH₄)₃] the BH₄ groups are doubly bonded to the central aluminum atom and distinct bridging and terminal ¹H signals were expected. However, only one ¹H resonance was detected. ²⁷Al decoupling and observation of the ¹¹B spectrum proved that an intramolecular process equilibrated the hydrogen atom environments, but the same four hydrogen atoms remained attached to each boron atom.

2.1 Unidentate Ligands

2.1.1 Three Coordination

An atom bonded to three groups in a pyramidal geometry and possessing a lone pair of electrons may undergo a spontaneous inversion of configuration, generally via a planar transition state (Scheme 3). This process may be studied by DNMR, providing its rate matches the NMR timescale and it causes an exchange between different chemical environments. Thus pyramidal inversion of ML₃ groups cannot be studied, whereas species ML₁L₂L₃ where one of the ligands (L) is a diastereotopic group such as isopropyl or C₆H₅CH₂, may be investigated. Barriers to inversion vary widely according to the central atom.¹⁹ For instance in Group V, barriers increase in the order N < P < As, and in Group VI the order is O < S < Se < Te. Nitrogen and sulfur atoms provide the greatest number of examples of NMR-detectable inversion.¹⁷ Sulfur inversion rates are usually detectable only when the atom is coordinated to metals, whereas in many cases phosphorus atoms are stereochemically rigid at all accessible temperatures.

2.1.2 Four Coordination

The favored geometry here is the regular tetrahedron, but in certain cases the square planar form may have a similar energy

Scheme 3

and interconversion of these forms may occur, as in the case of bisphosphine complexes of nickel(II) halides, (R₃P)₂NiX₂.²⁰

The other common geometry for four coordination is the trigonal bipyramid, where one equatorial position is occupied by a lone pair. This structure is adopted by SF₄ but is only evident at about -50 °C when its ¹⁹F spectrum consists of two 1 : 2 : 1 triplets confirming the C_{2v} structure. At higher temperatures rapid exchange of axial and equatorial ¹⁹F atoms occurs.²¹ Related compounds and metal complexes of SF₄ are similarly fluxional.

2.1.3 Five Coordination

Stereochemical nonrigidity is a common and unifying feature of five-coordinate trigonal bipyramidal structures,²² energy barriers being low (<40 kJ mol⁻¹) and sometimes too low for NMR detection. PF₅ is the classical example. Its trigonal bipyramidal structure has been established by electron diffraction, but its ¹⁹F NMR spectrum at all temperatures above about -150 °C consists of a single chemically shifted signal (with ³¹P–¹⁹F splitting) indicative of a low-energy exchange process which permutes all fluorine positions. The favored mechanism is the Berry pseudorotation mechanism. This is shown in Scheme 4 for the case when F³ acts as the pivot and exchanges axial (1,2) and equatorial (4,5) fluorine atoms. Direct evidence for this type of fluxion was obtained from the ¹⁹F spectra of PF₃Cl₂ and PF₃Br₂.

While most ML₅ species undergo fluxionality which is too rapid for NMR detection, cationic transition metal complexes of the type M[P(OR)₃]₅ⁿ⁺ (M = Co^I, Rh^I, Ir^I, Ni^{II}, Pd^{II}, or Pt^{II}) are a notable exception and detailed total bandshape studies have been carried out.²³ Complexes of type ML₄X are also stereochemically nonrigid, the rate of fluxionality being very dependent on whether the unique X ligand occupies an equatorial or axial site. In the hydride species ML₄H, the H ligand is in an axial position and energy barriers to fluxion are low, e.g. Rh(PF₃)₄H, 36 kJ mol⁻¹, and Rh(POEt₃)₄H, 30 kJ mol⁻¹.

In ML₃X₂ complexes with C_{2v} symmetry, the fluxionality depends on the electronic natures of X and L. Thus, PF₃Cl₂ and PF₃Br₂ are nonrigid, whereas PF₃Me₂ is rigid. Energy differences between trigonal bipyramidal and square pyramidal geometries may sometimes be very small, as illustrated by the complexes Pd(PMe₃)₃X₂. When X = Br or I trigonal bipyramidal structures occur, but when X = Cl a distorted

Scheme 4

square pyramidal geometry is adopted. The fluxional process in this case is an intermolecular double-replacement mechanism.

2.1.4 Six Coordination

The octahedral geometry of six coordination is exceptionally stable and stereochemical nonrigidity is here the exception rather than the rule. An example is the molecule $\text{C}_6\text{H}_5\text{SF}_5$, the ^{19}F spectrum of which consists of an AB_4 pattern at all accessible temperatures. Any fluxional rearrangement would have an associated barrier of $>120 \text{ kJ mol}^{-1}$. For this reason the regular octahedral structure of SF_6 is assumed to be rigid.²² In this instance, NMR is *not* a useful kinetic probe because all ^{19}F environments are equivalent irrespective of whether the structure is static or dynamic.

Metal dihydride complexes of the type MH_2L_4 ($\text{M} = \text{Fe}$ or Ru ; $\text{L} = \text{phosphine}$) form an important example of nonrigid species. They adopt a *cis*-octahedral stereochemistry but with considerable distortions from regular octahedral geometry. The complex $\text{FeH}_2[\text{P}(\text{OEt})_3]_4$ was the focal point of a classic DNMR study.²⁴ Variable temperature ^1H NMR spectra are shown in Figure 1. Certain lines remain sharp throughout and these are clearly due to spin transitions unaffected by the ligand permutations. A full analysis of the problem shows that the total of 48 permutations fall into four basic sets. NMR bandshapes based on all four sets, plus a fifth set for random exchange, were computed and compared with the experimental spectra. Only the set corresponding to a tetrahedral jump mechanism gave very close agreement. This mechanism involves FeH bending, which moves a single H

Figure 1 Observed and calculated 220 MHz ^1H NMR spectra (hydride region) of $\text{FeH}_2[\text{P}(\text{OEt})_3]_4$ as a function of temperature. The results are shown for first order and complete calculations using the basic computational set IV. (Reproduced by permission of The American Chemical Society from J. P. Jesson and P. Meakin, *Acc. Chem. Res.*, 1973, **6**, 269)

ligand from a tetrahedral face to a tetrahedral edge with concomitant increase in the associated P–Fe–P angle. The results of the DNMR study gave the activation parameters, $\Delta G^\ddagger$ (289 K) = 57.3 kJ mol⁻¹, $\Delta H^\ddagger$ = 46.4 kJ mol⁻¹ and $\Delta S^\ddagger$ = -36.8 J K⁻¹ mol⁻¹.

An enormous variety of six-coordinate complexes with unidentate ligands exist. Some of these exhibit fluxionality involving ligand site exchange, but rather more involve ligand-based movements (inversions, rotations and isomerizations). ML₅L' complexes are widespread, particularly when M is a transition metal, L is carbonyl and L' is a nitrogen or sulfur donor ligand, e.g. [M(CO)₅L'] (M = Cr, Mo, or W) complexes. Many such complexes are fluxional. For example, if L' contains an azo or dithio linkage then 1,2-metallotropic shifts can occur [equations (1) and (2)],²⁵ and these are detectable by NMR by the exchange effects on the R protons. In general, energies of these metal commutations are quite high [$\Delta G^\ddagger$ (298 K) = 55–80 kJ mol⁻¹], and in some cases the two-dimensional EXSY method is preferable to one-dimensional bandshape analysis. 1,3-Metallotropic shifts are also a common fluxional type, typical examples being complexes of naphthyridine [equation (1)] and 2,4-dithiapentane [equation (4)].²⁵

Complexes of type MX₃L₃ can exist in both meridional (*mer*) and facial (*fac*) forms, but *mer* $\rightleftharpoons$ *fac* exchange is normally too slow for detection. Complexes of the type MXL₃L'₂ include platinum(IV) complexes [PtXMe₃L'₂] and isoelectronic rhenium(I) complexes [ReX(CO)₃L'₂], in both cases X being a halogen. Both series form *fac* complexes with nitrogen or sulfur as donor ligands. In bis(pyridazine) complexes, 1,2-M–N shifts occur on each ligand. In substituted pyridazine complexes, exchange between four linkage isomers has been measured by bandshape analysis and two-dimensional EXSY experiments (Scheme 5).²⁶

2.1.5 Seven Coordination

Seven-coordinate complexes with unidentate ligands are normally highly nonrigid and NMR cannot always identify the static structure, usually a pentagonal bipyramid of D_{5h} symmetry (e.g. IF₇). Fluxional behavior in complexes of the types MH₃L₄ and MH₂L₅ has, however, been detected. The case of CrH₂[P(OMe)₃]₅ is illustrative.²⁷ The static spectrum (excluding OMe signals) comprises an AB₂CC'XX'

Scheme 5

spin system. From a full permutational analysis 16 basic sets of permutations of hydride and phosphine ligands were calculated. NMR bandshapes were calculated for all sets, but only two gave a reasonable matching with experimental spectra (Figure 2). The preferred mechanism involves simultaneous exchange of the two axial phosphines with two of the equatorial phosphines, the total fluxion corresponding to permutation of the CrP₅ framework related to the Berry pseudorotation process in five-coordinate complexes. The computation of the NMR bandshapes for this complex was far from trivial since the ³¹P–{¹H} and ¹H spectra were five- and seven-spin problems, respectively. The work represents one of the most ambitious applications of DNMR total bandshape analysis.

Fluxional energy barriers decrease quite rapidly as the coordination number of the metal complexes increases beyond seven, and in most cases limiting slow exchange spectra are not accessible.

2.2 Bidentate Ligands

2.2.1 Four Coordination

The most common types are the bisbidentate complexes which possess either planar or tetrahedral structures. In the case of nickel(II) complexes, rapid interconversion between the two forms commonly occurs, namely planar (*S* = 0) $\rightleftharpoons$ tetrahedral (*S* = 1). This equilibrium has been studied extensively for aminotroponeimine, salicylaldimine, and β -ketoamine complexes. The paramagnetism of the tetrahedral form causes large contact shifts of the ¹H or ¹³C signals. The mechanism is thought to involve a *trans* planar intermediate via a diagonal twist process (Scheme 6). Bischelate complexes of the type M(L–L')₂ existing solely in the tetrahedral form may also display inversion of configuration ($\Delta \rightleftharpoons \Lambda$) which may be followed by NMR. For further details the reader is referred to the monograph by La Mar et al.²⁸

2.2.2 Six Coordination

2.2.2.1 Monobidentate. Many fluxional complexes fall into this category. Some early studies concerned

Figure 2 Experimental 90 MHz ^1H spectra (hydride region) of $\text{CrH}_2[\text{P}(\text{OMe})_3]_5$ compared with theoretical spectra based on permutational sets 9 and 10. (Reproduced by permission of The American Chemical Society from F. A. Van-Catledge, S. D. Ittel, and J. P. Jesson, *Organometallics*, 1985, 4, 18)

Scheme 6

titanium(IV) complexes of the type $\text{RTiCl}_3(\text{L}-\text{L})$ where $\text{R} = \text{Me}$ or OMe and the bidentate ligand $(\text{L}-\text{L})$ is of the type $\text{XCH}_2\text{CH}_2\text{Y}$ with $\text{X}, \text{Y} = \text{OMe}, \text{SMe},$ or NMe_2 .²⁹ These complexes can exist as *mer* or *fac* structures; the *mer* forms exchange as shown in equation (5). The mechanism is either via a five-coordinate dissociative intermediate or a ligand rotation via a seven-coordinate

intermediate. The latter mechanism occurs in the complexes $[\text{PtXMe}_3(\text{L}-\text{L})]$ and $[\text{ReX}(\text{CO})_3(\text{L}-\text{L})]$ ($\text{X} = \text{halogen}$; $\text{L}-\text{L} = \text{thioethers}$ of the type $\text{MeSCH}_2\text{CH}_2\text{SMe}$, corresponding selenoethers and mixed thio/selenoethers). These complexes display multiple types of fluxionality, namely pyramidal inversions of the coordinated sulfur or selenium atoms, ligand 180° rotations, and, in the case of the platinum(IV) complexes, correlated PtMe_3 120° rotations. These fluxions were separately measurable in the complexes $[\text{PtXMe}_3(\text{MeSCH}_2\text{SCH}_2\text{SMe})]$, where all methylene ^1H signals become averaged at elevated temperatures. Pyramidal sulfur inversion leads to AB patterns for the diastereotopic methylene groups, but only a 180° ligand rotation process can lead to the additional A/B averaging [equation (6)].²⁵

The use of ligands with redundant but potential donor atoms greatly increases the probability of fluxionality. This has been demonstrated for the complexes $[\text{PtXMe}_3\{(\text{MeS})_2\text{-CHCH}(\text{SMe})_2\}]$, where the ligand possesses four sulfur donors but only two are involved in coordination at any time. However, a 1,3-Pt-S pivot fluxion occurs whereby all sulfur atoms become involved in the bonding.¹⁰ Transition metal complexes of heterocyclic nitrogen donor ligands are widespread. Recently, a novel type of fluxionality has been shown to exist in bidentate chelate complexes where the ligand contains a third nitrogen donor. Such an example is 2,2':6',2''-terpyridine (terpy) when complexed with the metal moieties PtXMe_3 or $\text{ReX}(\text{CO})_3$. These complexes are fluxional as a consequence of the ligand trying, but failing, to adopt its more usual terdentate binding mode.¹⁷ Pyridylpyrazole ligand complexes are similarly fluxional and the complex $[\text{ReBr}(\text{CO})_3(\text{Me}_2\text{-bppy})]$ [bppy = 2,6-bis(pyrazol-1-yl)pyridine] [equation (7)] has been studied in detail by means of both one-dimensional bandshape analysis and two-dimensional EXSY. In this case, the fluxion exchanges chemically distinct complexes by a process which involves a twist of the metal moiety through the N-Re-N angle via a seven-coordinate intermediate. The ^1H two-dimensional EXSY spectrum at -10°C shows exchange between pairs of ring hydrogen atoms with the exception of hydrogens J and S which are virtually isochronous (Figure 3)³⁰ Such 1,4-M-N shifts appear to be a common feature of complexes of aromatic nitrogen heterocycles with redundant nitrogen donors.

2.2.2.2 Bisbidentate. Complexes of four main types fall into this category, namely $\text{M}(\text{L-L})_2\text{X}_2$, $\text{M}(\text{L-L}')_2\text{X}_2$, $\text{M}(\text{L-L})_2\text{XY}$, and $\text{M}(\text{L-L}')_2\text{XY}$, where X and Y denote unidentate ligands. Most studies have been performed on the complexes $\text{M}(\text{L-L})_2\text{X}_2$, where (L-L) are β -diketonates and X are halides. Both *cis* and *trans* isomers can exist, the *cis* isomer usually being preferred. In contrast, the complexes

$\text{M}(\text{L-L}')_2\text{X}_2$ can exist as five geometric isomers. The first such complex to be examined in detail was $[\text{Ti}(\text{bzac})_2\text{X}_2]$ (X = F, Cl, or Br; bzac = benzoylacetate), but no mechanistic information could be obtained from the DNMR bandshape changes.³¹

2.2.2.3 Trisbidentate. The study of the stereochemical nonrigidity of octahedral tris chelate complexes represents a major challenge to DNMR techniques. This is a large and complex subject and space does not allow other than a brief mention of its scope. The reader is referred to the article by Holm³¹ for more detail on early work in this field.

The complexes of symmetrical chelates, $\text{M}(\text{L-L})_3$ do not possess geometrical isomers and their only source of non-rigidity is inversion of configuration, $\Delta \rightleftharpoons \Lambda$. This may be followed by NMR, providing that the ring substituents contain a diastereotopic group. Complexes of the type $\text{M}(\text{L-L}')_3$ can exist as *cis* or *trans* isomers, each of which is enantiomeric. The isomers can undergo both inversion ($\Delta \rightleftharpoons \Lambda$) and isomerization (*cis* $\rightleftharpoons$ *trans*) by twist or bond-rupture mechanisms. In the case of β -diketonate complexes, isomerization generally occurs via a bond-rupture mechanism. The case of $[\text{Al}(\text{pmhd})_3]$ (Hpmhd = 1-phenyl-5-methylhexane-2,4-dione) has been examined closely.³² Variable temperature spectra of the methyl signals were compared with computer-simulated spectra based on a variety of fluxional mechanisms and signal assignments. Three mechanisms produced satisfactory fits between experimental and theoretical spectra. The DNMR problem involved a 16-site exchange matrix. The degree of complexity of the problem can be appreciated from the fact that there are 720 different ways of assigning the methyl signals in the slow exchange spectrum!

Other tris chelate ligand complexes which have been examined in detail by DNMR are complexes of substituted tropolonates and dithiocarbamates.

3 FLUXIONAL ORGANOMETALLIC COMPOUNDS

3.1 Rotations about Metal-Ligand and Metal-Metal Bonds

The diversity of bonding types in organometallic chemistry is reflected in the wide range of rotation rates of M-L and M-M bonds, where both steric and electronic factors appear to play distinctive roles.³³

3.1.1 σ Metal-Carbon Bonds

The degree of double bond character of M-C bonds can vary enormously. In the case of carbene ligands this can cause the free energy of activation for rotation to rise to around 100 kJ mol^{-1} . However, there is no simple relationship between the degree of double bond character and the size of the rotational barrier, as exemplified by the complexes $[(\eta\text{-C}_5\text{H}_5)(\text{CO})_2(\text{Et}_3\text{P})\text{M-CH}_2]^+$: when M = W, the energy barrier is about 35 kJ mol^{-1} , whereas when M = Mo the barrier is too low for NMR estimation.³⁴

3.1.2 Metal-Alkene and Metal-Alkyne Bonds

NMR techniques have been applied very extensively to these rotations. Two fundamentally different processes may

Figure 3 The ^1H two-dimensional EXSY spectrum of $[\text{ReBr}(\text{CO})_3(\text{Me}_2\text{-bppy})]$ in CD_2Cl_2 at -10°C showing the effects of the 1,4-fluxional shift. The mixing time for the experiment was 0.5 s. (Reproduced by permission of The Chemical Society from E. W. Abel, K. A. Hylands, M. D. Olsen, K. G. Orrell, A. G. Osborne, V. Šik, and G. N. Ward, *J. Chem. Soc., Dalton Trans.*, 1994, 1079)

be envisaged (see Scheme 7). In (a) there is rotation about an axis between the metal and the center of the $\text{C}=\text{C}$ bond, whereas in (b) the $\text{C}-\text{C}$ bond itself acts as the rotation axis. In highly symmetrical molecules these two mechanisms are not distinguishable, but there is extensive evidence for pathway

(a). Such a mechanism operates in the carbonyl nitrosyl complexes (1) and (2). In (2) each ethene hydrogen is in a unique environment which at low temperature results in an ABCD spectrum. The observation³⁵ of collapse to an $\text{AA}'\text{BB}'$ spectrum on warming is in accord with rotation about the

Scheme 7

metal–alkene bond. Any additional rotation about the C=C axis would have produced further collapse to an A₄ spectrum.

Alkene–metal rotations have free energies of activation ranging between about 30 and 80 kJ mol^{−1}. A similar range is associated with alkyne–metal rotations.

3.1.3 Metal– η -Enyl Bonds

The simplest η -enyl metal complexes are those containing η -allyl groups. A typical example is shown in equation (8).³⁶ Here the influence of the R group is surprisingly large: when R = H, E_a = 52 kJ mol^{−1}, whereas when R = Me, E_a = 70 kJ mol^{−1}. Numerous variable temperature NMR studies have demonstrated rotations in acyclic (e.g. pentadienyl) and cyclic (e.g. five-, seven-, and eight-membered) poly(enyl) metal complexes. Several of these have such low activation energies that they have been characterized by solid state CP MAS experiments. In the case of cyclopentadienyl (Cp) ligands, ring substitution can greatly hinder the ligand rotation, even in solution. For example, in 1,1',2,2',4,4'-hexakis(trimethylsilyl)ferrocene³⁷ the barrier to mutual rotation of the Cp rings can be measured by NMR ($\Delta G^\ddagger$ = 46 kJ mol^{−1}), in contrast to ferrocene itself where the barrier is too low for detection by solution NMR studies and is <10 kJ mol^{−1} in the solid state.

3.1.4 Metal Polyenes and Arenes

An example of rotation of the simplest polyene, butadiene, is in the complex (η -C₄H₆)Fe(CO)₃ (**3**). At room temperature only one carbonyl signal is observed in the ¹³C spectrum, but, on cooling, the slow rotation region can be reached. The ¹H spectra show that the *syn* and *anti* terminal hydrogen atoms do not exchange, showing the molecules to be conformationally labile but configurationally stable. There have been numerous other studies of rotations of acyclic η^4 -dienes, cyclic η^4 -dienes, and cyclic η^6 -trienes about metal atoms. In general,

the rotations are quite facile with $\Delta G^\ddagger$ values usually falling in the range 30–50 kJ mol^{−1}.

Rotations about metal–arene bonds are extremely facile, even in the solid state. For the compound Cr(η -C₆H₆)(CO)₃, lineshape measurements gave³⁸ an activation energy, E_a of 3.4 kJ mol^{−1}, whilst T_1 measurements (in good agreement) gave a value of 4.2 kJ mol^{−1}. Ring substitution predictably raises the energy barrier to rotation. Thus for [Cr(η -Et₆C₆)(CO)₂(CS)] in solution the barrier is about 35 kJ mol^{−1}, the ethyl groups needing to twist out of the path of the carbonyls so that the Cr(CO)₂(CS) moiety may rotate. In the complexes [M(η^6 -C₆H₅Me)(CO)₃] (M = Cr or Mo), metal–arene rotations are too fast for detection in solution but are measurable by ¹³C CP MAS spectroscopy in the solid. Here, however, the arene rings are locked in the lattice and the detectable rotations are due to the spinning of the M(CO)₃ groups.³⁹ The highly facile rotation of the metal–arene system is associated with the full delocalization of the aromatic ring. In cases where the ring has a localized hexatriene character, the barrier to rotation becomes accessible to solution NMR studies.

3.1.5 Metal–Metal Bonds

Many examples of rotations about metal–metal bonds have been observed and characterized by NMR spectroscopy, but their activation energies are difficult to rationalize, since values do not increase steadily with bond order. For instance, in the case of rotation about tungsten–tungsten bonds, in [W(η -C₅H₅)(CO)₃]₂ and [WMe(NEt₂)₂]₂ activation energies are 68 and 89 kJ mol^{−1}, this being a surprisingly small difference for rotations about formally single and triple metal–metal bonds, respectively. Many heteronuclear metal–metal bonds have also been investigated, one such case⁴⁰ being rotation about the W=As bond in (**4**) where ¹H spectra show coalescence of the two *t*-Bu signals on rotation, $\Delta G^\ddagger$ being estimated as 46 kJ mol^{−1}. Clearly, in all these metal–metal bond rotations the measured rates are a complex function of both electronic and steric factors.

3.2 Metallotropic Shifts

The first observations of metallotropic shifts in the mid-1950s launched the whole field of fluxionality in organometallic compounds. It was in 1956 that the unexpected temperature

Scheme 8

dependence of the ^{13}C spectra of $[\text{Fe}(\sigma\text{-C}_5\text{H}_5)(\eta\text{-C}_5\text{H}_5)(\text{CO})_2]$ led to the radical proposal, for that time, that whilst the molecule was static at about -80°C , at higher temperatures the $[\text{Fe}(\eta\text{-C}_5\text{H}_5)(\text{CO})_2]$ moiety migrated around the $\sigma\text{-C}_5\text{H}_5$ ring by a series of [1,2]-shifts (Scheme 8). A similarly important observation was made in 1959 when the allyl Grignard reagent was shown to be fluxional [equation (9)] since its ^1H spectrum consisted of only two instead of the expected four signals. The mechanism here involves rapid [1,3]-shifts of the MgX group across the allyl group, with free rotation about the C–C single bond.

3.2.1 σ -Cyclopentadienyls

The sigmatropic shift of metals and metalloids around the cyclopentadienyl ring system, in addition to being the first organometallic fluxion to be detected by NMR spectroscopy, is also now one of the most common. The shift, illustrated in Scheme 2, has been observed for a remarkable range of metals and metalloids such as B, In, Si, Ge, Sn, As, Sb, Cu, Hg, Ti, Cr, Mo, Fe, Ru, Pd, and Pt. Distinction between [1,2]- and [1,3]-shifts around the ring is a subtle and challenging problem in DNMR spectroscopy, and has been the subject of much debate in recent years. The weight of evidence strongly favors [1,2]-shifts in most cases, and in some the evidence is definitive. Such an example is the silylcyclopentadiene (**5**). The chiral silicon atom produces anisochronicity among the C-2,5 and C-3,4 carbon pairs in the low-temperature ^{13}C spectra. At higher temperatures the C-2 and C-5 signals coalesce more rapidly with C-1 then do C-3 and C-4. A full bandshape analysis of this five-site exchange problem demonstrates that the [1,2]- and [1,3]-pathways are fully distinguishable and that only the [1,2]-shift case fits the observed ^{13}C spectra.⁴¹

When there are multiple cyclopentadienyl rings attached to one metal it is conceptually easier to view the rings as rotating with respect to the metal. Thus, in $(\sigma\text{-C}_5\text{H}_5)_3\text{As}$ all three rings migrate by [1,2]-shifts on the arsenic atom. Such situations may be further complicated by ligand role exchange. Thus, in $[\text{Ti}(\eta\text{-C}_5\text{H}_5)_2(\sigma\text{-C}_5\text{H}_5)_2]$ (Figure 4)⁴² the lowest energy process is the [1,2]-shift of the $\sigma\text{-C}_5\text{H}_5$ rings, but there is evidence of [1,3]-shifts as a minor pathway. At higher temperature all ^1H signals collapse to a singlet, indicating

the rapid interchange of roles of the σ - and η^5 -bonded rings. This occurs readily in solution above about 333 K, but is substantially retarded in the solid state. In contrast, the $\sigma\text{-C}_5\text{H}_5$ migration occurs with similar facility in both solid and solution phases.

3.2.2 σ -Cycloheptatrienyls

Thermal sigmatropic shifts for metal cycloheptatrienyl complexes are predicted, by the Woodward–Hoffmann rules, to be of the [1,5]-type, and this has been confirmed by NMR in compounds such as $\text{Sn}(\sigma\text{-C}_7\text{H}_7)\text{R}_3$. At first sight such shifts appear to be less likely than the ‘shortest distance’ [1,2]-shift, but the folded conformation of the C_7H_7 ring allows the [1,5]-shift to be only a marginally more distant migration than the [1,2]-shift. For $[\text{Re}(\text{CO})_5(\sigma\text{-C}_7\text{H}_7)]$, however, the situation is reversed and elegant spin saturation experiments⁴³ have shown the migration to be of the [1,2]-type. There is clearly a delicate balance between ‘shortest distance’ and Woodward–Hoffmann criteria, and in some cases more than one pathway is followed. For example, in $\text{Rn}(\eta\text{-C}_5\text{H}_5)(\eta^1\text{-C}_7\text{H}_7)(\text{CO})_2$ both [1,2]- and [1,5]-shifts occur at comparable rates.⁴⁴

3.2.3 Noncyclic σ -Enyls

The σ -allyl complexes are the simplest example here and the overall fluxion is a [1,3]-shift as described for the Grignard complexes [equation (9)]. Similar migrations have been observed for other elements, notably B, Hg, Ti, and Pd.

[1,5]-Suprafacial shifts have been detected by spin saturation transfer and line-broadening studies of a hexadiene tin compound [equation (10)]. This symmetry-allowed shift has an activation energy of 81.5 kJ mol^{-1} .

3.2.4 Metal Migrations on π Systems

When a metal is π -bonded to an organic moiety there is considerable potential for metal migrations and large numbers of π -bonded transition metal organometallics have been thus characterized by NMR. Illustrative examples of six-, seven-, and eight-membered ring complexes are given below.

A six-membered ring case is represented by the η^6 -naphthalene $\text{Cr}(\text{CO})_3$ complex where NMR spectra show the metal moiety to move between the two rings, as shown in equation (11).⁴⁵ A similar shift occurs between the six- and eight-membered rings in benzocyclooctatetraenetricarbonyl chromium.

Seven-membered ring cycloheptatrienyl complexes may be η^3 , η^4 , or η^5 bonded, but all types have been shown to undergo [1,2]-shifts. The case of the η^4 complex $[\text{Fe}(\text{CO})_3(\eta^4\text{-C}_7\text{H}_8)]$

Figure 4 (a) ^{13}C CP MAS spectra of $\text{Ti}(\text{C}_5\text{H}_5)_4$ at various temperatures, showing the isotropic resonances. Signals (●) are spinning sidebands. (b) Simulation of the centerband spectrum using the program DNMR4. A simple five-site exchange model was used and exchange was modeled with [1,2] or random shifts. (Reproduced by permission of The American Chemical Society from S. J. Heyes and C. M. Dobson, *J. Am. Chem. Soc.*, 1991, **113**, 463)

Scheme 9

is illustrated in Scheme 9, the mechanism invoking an η^2 16-electron intermediate.

Cyclooctatetraene (COT) is the main example of eight-membered π systems. When it is η^2 bonded to metals no metal migration is detectable, whereas all η^4 -COT compounds are highly fluxional. In the compound $(\eta^4\text{-COT})\text{Ru}(\text{CO})_3$, the ^1H spectrum at ambient temperatures is a singlet, but this changes

to a complex $\text{AA}'\text{BB}'\text{CC}'\text{DD}'$ spectrum at about -150°C , the different collapse rates for different proton pairs firmly establishing a [1,2]-shift mechanism.⁴⁶ The commutation of the $\text{M}(\text{CO})_3$ moiety in $[(\eta^6\text{-COT})\text{M}(\text{CO})_3]$ ($\text{M} = \text{Cr}$ or W) has been studied extensively, originally by magnetization transfer experiments⁴⁷ and latterly by ^1H and ^{13}C two-dimensional EXSY experiments.⁴⁸ Even now the transition state for these migrations cannot be precisely defined, since both [1,2]- and [1,3]-shifts occur at comparable rates. When $\text{M} = \text{W}$ both shifts are almost equally favored, whereas when $\text{M} = \text{Cr}$ the [1,3]-pathway is slightly preferred.

Examples of interesting fluxional π -enyl metal complexes are structures (6)–(8). In (6) the static structure produces an $\text{A}_2\text{B}_2\text{X}$ ^1H spectrum showing distinct *syn* and *anti* protons. On warming, these signals collapse to an A_4X spectrum, this

being attributed to a π - σ - π mechanism whereby the metal effectively moves from one face of the allyl ligand to the other. An interesting extension to this shift occurs in η^3 -benzyl complexes such as (7) where the benzene double bonds are frozen due to the allylic metal bond. On warming the complex the ^1H spectrum changes as a result of a ligand 'flip-over' analogous to that for allyl groups. The ^1H spectra of (8) change from three singlets (relative intensities 2:1:1) to one singlet on warming. This is attributed to the $\text{Fe}(\text{CO})_4$ moiety moving between all four available alkene faces of the allene structure, presumably by the metal moving to either face of the adjacent double bond by a [1,2]-shift with a simultaneous 90° rotation about the allene axis, and then back again in a type of corkscrew shuttle motion.⁴⁹

3.3 Miscellaneous Rearrangements

The diversity of fluxional processes in organometallic compounds, as revealed by NMR experiments, is enormous and the examples chosen above are simply representative of some of the major types. As the size of organometallic species increases so does the number of possible fluxional modes. In metal cluster compounds, for example, the many types of skeletal rearrangement and ligand migration (e.g. carbonyl exchanges) which can occur have been characterized primarily by NMR methods.

In many systems, stereochemical nonrigidity manifests itself in conformational changes within ligands (e.g. hindered internal rotations, site inversions, or ring reversals) rather than exchanges between ligands. Again, NMR has been invaluable in revealing and quantifying rates of such processes.

This article can only hint at the enormous contribution NMR has made to our understanding of stereochemical nonrigidity in molecules. Readers requiring more detailed literature coverage should see the regular reviews *Rearrangements, Intramolecular Exchanges and Isomerizations of Organometallic Compounds*,⁵⁰ and *Dynamic NMR Spectroscopy in Inorganic and Organometallic Chemistry*.¹⁷

1 INTRODUCTION

NMR spectroscopy was applied to gas samples very early in its history. In 1946, Purcell, Pound, and Bloembergen reported the first gas phase NMR study.¹ They measured the nuclear spin–lattice relaxation rate constant, T_1 , of H_2 gas at 10 atm and, based on the calculated correlation time, suggested that the rotationally inelastic collision cross section of H_2 is smaller than the hard sphere cross section. During the next 25 years, applications of NMR spectroscopy to gases were relatively uncommon. A review written by Govil discusses NMR applications to gases prior to 1972.² Because of sensitivity limitations, sample pressures above 1 atm were required, and most studies were concerned with density dependent chemical shifts and nuclear spin–lattice relaxation of diatomic and small polyatomic molecules. A few years after Govil's review, spectrometers employing superconducting magnets became available, making it possible to study gases below ambient pressure and to study spectra of many more nuclei in the gas phase. Now it is possible to observe spectra of samples at pressures of a few torr, and NMR spectroscopy can be used successfully to address a variety of chemical and physical properties and processes in the gas phase. Several reviews have recently appeared. Jameson reviewed recent gas phase NMR applications in 1991,³ and Armstrong reviewed gas phase NMR relaxation studies in 1987.⁴ True and Suarez reviewed gas phase NMR studies of conformational processes in 1994.⁵ The present article focuses on selected chemical applications of gas phase NMR spectroscopy.

Gas phase equilibrium constants and rate constants of chemical exchange processes can, in some cases, be obtained from NMR studies, with an accuracy comparable with that obtained in the best liquid phase studies. Since intermolecular effects are minimal at the low pressures which can be studied with current NMR instrumentation, gas phase conformational equilibrium constants obtained from NMR experiments can be directly compared with theoretical calculations for isolated molecules. Comparisons with equilibrium constants obtained for condensed phase samples provide a critical test of theoretical methods of calculating solvent effects. NMR

spectroscopy has been used to determine rate constants for chemical exchange processes in the gas phase as a function of pressure as well as temperature. At high pressures, unimolecular rate constants which can be compared with corresponding rate constants in solutions are obtained. At lower pressures, rate constants decrease with decreasing pressure and in many cases it has been possible to study the kinetics of chemical exchange processes in the low-pressure bimolecular region and to address questions about the microscopic dynamics of these processes.

Gases and liquids produce qualitatively similar NMR spectra. For typical molecules which undergo chemical exchange, gas phase spin–lattice relaxation at pressures above a few hundred torr do not contribute appreciably to observed linewidths for spin- $\frac{1}{2}$ nuclei and under slow exchange conditions scalar coupling is as well resolved as it is in liquids. Gas phase spectra are offset a few parts per million from corresponding solution phase spectra of the same molecule due to differences in the bulk susceptibility of the sample. The magnitude and direction of the offset depends on the spectrometer field, sample shape, and orientation in the field and the sample composition.⁶ Gas phase coupling constants and relative resonance positions are similar but not identical in gases and liquids. In the gas phase, conformer chemical shifts have only small linear temperature and pressure dependences over the temperature and pressure ranges used in most conformational studies and so can facilitate analysis of exchange broadened lineshapes. In solutions, chemical shifts can have strong nonlinear temperature dependences which can complicate the analysis of exchange broadened lineshapes to yield reliable rate constants.

Gas and liquid phase nuclear spin–lattice relaxation rates and mechanisms are different. Most studies of T_1 for 1H in the gas phase have concluded that this nucleus relaxes primarily through spin–rotation interactions.^{3,4} In the gas phase, T_1 can vary considerably over the temperature and pressure range where conformational data are obtained. Spin–rotation coupling constants are larger for nuclei in small molecules resulting in faster relaxation. At 1 atm, the values of T_1 for 1H in NH_3 and benzene are 70 ms and 8 s, respectively.^{4–7} Carbon-13 spin–lattice relaxation in benzene gas below 1000 torr also occurs primarily through spin–rotation interactions.⁷ The T_1 of ^{13}C in benzene at 1 atm is about 1000 times shorter than in the liquid phase, a factor which greatly facilitates spectral acquisition. Efficient spin–rotation relaxation in the gas phase, however, usually makes it impossible to employ techniques which require dipolar relaxation.

Short NMR tubes are usually used in gas phase NMR experiments for better temperature control and to eliminate contributions to observed linewidths and relaxation rate constants from bulk diffusion of magnetized molecules out of the active volume during the acquisition time. Most commonly, 10 and 12 mm tubes have been used for samples at pressures below 1 atm, and heavy walled (2.2 mm i.d., 4 mm o.d) tubes have been used in the range 5–40 atm. With few exceptions, most gas phase NMR studies of conformational processes have utilized samples containing the molecule of interest which is of necessity present at a low partial pressure and varying pressures of inert bath gases. Inert gases increase T_1 and also provide a critical experimental variable for kinetic studies. NMR spectra of dilute gases are routinely obtained using superconducting high-resolution NMR spectrometers.

Proton chemical shifts have been measured for samples with partial pressures of less than 1 torr, while a few torr are generally required to produce exchange broadened lineshapes suitable for rate constant analysis. To date, gas phase chemical exchange studies have utilized ^1H , ^2D , ^{19}F , ^{13}C , ^{10}B , and ^{11}B , and gas phase studies of many other nuclei are also feasible.⁴ Some studies have utilized external lock materials or added several atmospheres pressure of a deuterated gas to provide a frequency lock. For studies where linewidths of 1 Hz are acceptable it is usually not necessary to use a frequency lock if total acquisition times are less than 1–2 hours. Longer acquisitions are feasible without sacrificing resolution if spectra are acquired in blocks and added manually or if the voltage in the Z_0 shim coil is ramped during the experiment to compensate for the small linear field drift encountered with most superconducting magnets.

2 EQUILIBRIUM CONSTANTS OF CHEMICAL EXCHANGE PROCESSES

NMR spectroscopy is especially well suited for studies of conformational equilibria in many cases. Spectroscopic absorption coefficients depend on transition dipole matrix elements as well as populations of absorbing species. Since dipole matrix elements for nuclear magnetic transitions are not significantly different for different conformers, relative intensities in NMR spectra are directly related to the relative populations of the absorbing species. Relative intensity temperature dependent NMR measurements can yield a complete set of thermodynamic parameters characterizing the equilibrium process. In contrast, values of electric dipole transition matrix elements for rotational, vibrational, and electronic transitions can be significantly different for different conformations of the same molecule, making it impossible to determine a conformational equilibrium constant from relative intensity measurements alone. Lifetimes must be long enough so that each species produces a distinct NMR spectrum, and this is a serious limitation which has been partially overcome by measuring fast exchange coupling constants and using these measurements to deduce the conformational equilibrium. Measurements of both relative intensities and coupling constants have been used to determine equilibrium constants in the gas phase.

Keto–enol tautomerism of β -diketones has been studied in the gas phase. Keto–enol conversion occurs via an intramolecular proton shift between the methylene carbon in the keto form and one of the carbonyl oxygens in the enol tautomer. The activation energy for this process in the gas phase is not known, but since equilibrium is established rapidly after temperature changes and since the system still produces slow exchange spectra at temperatures as high as 200 K, the barrier can be estimated to be between 100 and 175 kJ mol⁻¹. Harris demonstrated the feasibility of using gas phase NMR intensity measurements to determine keto $\rightleftharpoons$ enol equilibrium constants, K_{eq} , of acetylacetone and ethyl acetoacetate.⁹ A later gas phase NMR study reported the thermodynamic parameters characterizing keto–enol equilibria of acetylacetone, methyl acetoacetate, and ethyl acetoacetate.¹⁰ For all three molecules, gas phase keto $\rightleftharpoons$ enol K_{eq} values were obtained from integration of

Figure 1 Gas and solution phase equilibrium constant, $K_{\text{eq}} = [\text{enol}]/[\text{keto}]$, for the keto–enol tautomerism of acetylacetone as a function of temperature. Data on the upper line were obtained for a 200 torr gas sample and the data on the lower line were obtained for a neat liquid sample. (Reprinted by permission of the American Chemical Society from M. M. Folkendt, B. E. Weiss-Lopez, J. P. Chauvel, Jr., and N. S. True, *J. Phys. Chem.*, 1985, **89**, 3347)

^1H NMR spectra obtained between 373 and 445 K. Figure 1 shows equilibrium constants of acetylacetone gas and neat liquid as a function of temperature. For acetylacetone gas, $\Delta G_{298}^0(\text{E–K})$ is -9.2 ± 1.9 kJ mol⁻¹, $\Delta H^0(\text{E–K})$ is -19.5 ± 0.7 kJ mol⁻¹, and $\Delta S^0(\text{E–K})$ is -34.6 ± 1.9 J mol⁻¹ K⁻¹. The corresponding values in the neat liquid are -3.8 ± 1.2 kJ mol⁻¹, -11.8 ± 0.5 kJ mol⁻¹, and -26.7 ± 1.3 J mol⁻¹ K⁻¹, respectively. A similar trend is observed for the keto $\rightleftharpoons$ enol equilibria of methyl acetoacetate and ethyl acetoacetate. The intramolecular hydrogen bond which is formed in the enol tautomer is primarily responsible for its lower energy. For all three molecules, in all phases the keto tautomer has the larger entropy, consistent with its lower torsional frequencies. $\Delta H^0(\text{E–K})$ is smaller in the neat liquid, possibly indicating that solvent interactions lower the energy of the more polar keto tautomer.

The *syn* $\rightleftharpoons$ *anti* conformational equilibrium of gaseous methyl nitrite ($\text{O}=\text{NOCH}_3$) was studied using ^1H NMR spectroscopy. The first study reported thermodynamic parameters which were obtained from direct integration of resolved *syn* and *anti* methyl proton resonances.¹¹ The limitations of the low conformer interconversion barrier and sample volatility restricted the observation of slow exchange spectra to temperatures between 193 and 223 K. Thermodynamic parameters are $\Delta H^0(\text{anti–syn}) = 4.2 \pm 0.2$ kJ mol⁻¹, $\Delta G^0(\text{anti–syn}) = 2.2 \pm 0.01$ kJ mol⁻¹, and $\Delta S^0(\text{anti–syn}) = 9.75 \pm 1.0$ J mol⁻¹ K⁻¹. The observed $\Delta S^0(\text{anti–syn})$ value agrees with previously determined rotational and vibrational frequencies. The largest factor contributing to the calculated entropy difference is the methyl internal rotation barrier, which is 8.77 kJ mol⁻¹ in *syn*-methyl nitrite and only 0.12 kJ mol⁻¹ in the *anti* conformer. Cordell et al. reported ab initio molecular orbital calculations which show that a favorable interaction between

a C–H bond of the methyl group and the nitrogen lone pair when the CH and N groups are eclipsed stabilizes the *syn* conformer and also results in its higher methyl group internal rotation barrier.¹²

Chemical shifts of larger alkyl nitrites were measured in the slow exchange limit. Lower vapor pressures restricted measurements of slow exchange conformer relative intensities. Changes in the conformer equilibria of methyl nitrite with temperature produce large temperature dependent shifts in the fast exchange resonance position, and thermodynamic parameters obtained for methyl nitrite from direct signal integrations agree with those obtained from measurements of chemical shifts in the fast exchange limit. Therefore, fast exchange chemical shift measurements were used to obtain *syn* $\rightleftharpoons$ *anti* equilibrium constants of the larger nitrites.¹³ In the gas phase, the *syn*–*anti* conformer energy difference is smaller for the larger nitrites and the *anti* conformers have larger entropies than the corresponding *syn* conformers with the exception of isopropyl nitrite. These trends are also observed in alkyl nitrite solutions but here the entropies of the *syn* and *anti* conformers are more similar.

For relatively large molecules, long-range coupling constants can be measured in the gas phase with the same accuracy as in solution. Figure 2 shows the ^{19}F NMR spectrum at 376 MHz of 1,2-difluoroethane in the gas phase at 353 K obtained by Hirano et al.¹⁴ Nitrogen at a pressure of 1 atm was added to samples containing 507 torr of 1,2-difluoroethane, 47 torr of TMS, and 104 torr of CFCl_3 to increase T_1 and narrow the natural linewidth. The gas sample was contained in a 3 mm o.d. inner tube placed in a 5 mm o.d. outer tube containing $[\text{D}_6]\text{dimethyl sulfoxide}$ as a lock solvent. 3J coupling constants of 1,2-difluoroethane ranging from 2.78 to 25.69 Hz, with an estimated error of less than 0.002 Hz, were obtained by comparing simulated and observed spectra. They are consistent with a *trans*–*gauche* energy difference of 3.3 kJ mol^{−1}. Coupling constants have been obtained in the gas phase with similar accuracy for several other compounds. Analyzing long-range coupling constants to provide information about conformer populations and interconversion barriers is difficult. In addition to the difficulty of calculating coupling constants with current theory,¹⁵ there is a small intrinsic temperature dependence of coupling constants of molecules which do not exist as conformational mixtures,^{16,17} and it is not possible to separate the observed temperature dependence into intrinsic and conformationally dependent contributions. Despite these difficulties, large phase dependent differences in coupling constants are an indication of a phase dependent shift in the conformational equilibrium.

Hirano et al. also measured long-range coupling constants of gaseous 1,2-di[$^2\text{H}_3$]methoxypropane.^{18,19} Analysis of the second-order spectrum produced by this ABCX_3 spin system yielded $^3J(\text{AC})$ and $^3J(\text{BC})$ of 4.89 and 6.38 Hz, respectively. Assuming that 3J is 9.1 Hz for the antiperiplanar and 2.6 Hz for the synclinal form, based on results for 1-methoxypropan-2-ol, the observed coupling constants are consistent with G^+ and G^- conformers with relative energies 3.4 and −2.1 kJ mol^{−1} higher than the T conformer. Hirano et al. also determined that 1-methoxypropan-2-ol and 2-methoxyethanol are intramolecularly hydrogen bonded in the gas phase based on hydroxyl proton chemical shifts.^{18,19}

Pachler and Wessels measured the temperature dependence of the vicinal coupling constants of 1-bromo-2-chloroethane

Figure 2 Fluorine-19 NMR spectra (376 MHz) of 1,2-difluoroethane in the gas phase at 353 K. (a) observed, (b) simulated. (Reprinted by permission of the Royal Society of Chemistry from T. Hirano, S. Nonoyama, T. Miyajima, Y. Kurita, and H. Sato, *J. Chem. Soc., Chem. Commun.*, 1986, 606)

in the gas phase between 375 and 478 K.²⁰ Since the internal rotation potential function in the gas phase was known, it was possible to evaluate the coupling constants for the *trans* and *gauche* isomers which were then used to analyze solution phase data. Inomata and Abe recently obtained gas phase values of $^3J(\text{H,H})$ for 1,2-dimethoxyethane which ranged from 5.80 to 5.85 Hz between 398 and 443 K with an estimated error of less than 0.05 Hz.²¹ The observed gas phase ^1H – ^1H and ^{13}C – ^1H vicinal coupling constants were compared with those in nonpolar solvents, and the authors concluded that the *gauche* oxygen effect in 1,2-dimethoxyethane is due to intramolecular factors rather than interactions with solvent molecules.

3 GAS PHASE KINETICS OF CHEMICAL EXCHANGE PROCESSES

In solutions, chemical exchange processes invariably exhibit unimolecular kinetics, and in most cases transition state (TS) theory has provided a convenient framework for reporting kinetic parameters for these processes.⁸ In the gas phase, however, rate constants of chemical exchange processes are pressure dependent, and unimolecular kinetics are only observed at high pressures. The pressure dependence is due to competition between bimolecular deactivation,

and reaction of energized molecules (A^*),

where k_a , k_d , and $k(E)$ are the activating, deactivating, and internal energy dependent reaction rate constants. The macroscopic unimolecular reaction rate constant, k_{uni} , consistent with this mechanism is

$$k_{\text{uni}} = -\frac{1}{[A]} \frac{d[A]}{dt} = \int_{E^*=0}^E \frac{k(E)k_a/k_d}{1 + k(E)/k_d[M]} dE \quad (3)$$

which reduces in the high-pressure limit to $k_{\text{uni}} = k(E)k_a/k_d$, and in the low pressure limit to $k_{\text{uni}} = k_a[M]$.²² Accordingly, three pressure regions, unimolecular (high pressure), fall-off (intermediate), and bimolecular (low pressure), can, in principle, be observed for a gas phase chemical exchange process. Studies in each region provide different information about the process.

High-pressure unimolecular rate constants are most directly comparable to rate constants obtained in solutions. To a good first approximation, the temperature dependence of rate constants in the unimolecular region can be analyzed to provide Eyring parameters, i.e. $\Delta H^\ddagger$, $\Delta G^\ddagger$, and $\Delta S^\ddagger$, which can then be compared with those obtained for other molecules and with corresponding parameters in the liquid phase for the same molecule and also with theoretical calculations. Some precautions are needed in making these comparisons. First, it is not clear if transition state theory, which is the high-pressure limiting form of Rice–Ramsperger–Kassel–Marcus (RRKM) theory provides a valid description of all conformational processes under all conditions. Non-RRKM behavior can occur in either phase. Few conformational processes have been studied over the extensive pressure range in either the gas or solution phase required to provide a definitive test of RRKM theory. Also most solution phase studies of conformational processes have measured rate constants as a function of temperature at ambient pressure. These experiments do not allow the static and dynamic solvent effects to be separated. Solution phase studies under conditions of isoviscosity, obtained by applying pressure to the sample, show that isobaric and isoviscosity activation parameters can differ. Isoviscosity measurements are more directly comparable with gas phase results.²³

Rate constants of many chemical exchange processes at or near the unimolecular limit have been determined using NMR spectroscopy and, despite the possible complication described above, several conclusions can be drawn. The earliest kinetic study of a conformational process using NMR spectroscopy was a study of the internal rotation in *N,N*-dimethylnitrosamine reported by Harris and Spragg.²⁴ The CW ^1H NMR spectrum of the gas at 100 MHz is at intermediate exchange at 160°C while that of the neat liquid is at slow exchange, consistent with a gas phase barrier about 8.4 kJ mol⁻¹ lower than in the neat liquid. Additional studies have also demonstrated that gas and solution phase kinetic parameters can be significantly different. Internal rotation has been studied for several symmetrically substituted amides.^{25–32} In each case, exchange broadened ^1H spectra were obtained for samples containing the amide at its vapor pressure and several atmospheres of an inert gas; measurements were made at several pressures to ensure that the rate constants were at the unimolecular limit. Feigel measured rate constants for internal rotation of *N,N*-dimethylacetamide at bath gas pressures ranging from 0.5 to 24.5 atm which were found to be independent of pressure.²⁹ Other amides

Figure 3 Carbon-13 NMR spectra of *N,N*-dimethylformamide. Spectra are Fourier transforms of the sum of about 2000 transients obtained at 50 MHz using a 99% ^{13}C enriched sample at its vapor pressure. (Reprinted by permission of the American Chemical Society from B. D. Ross and N. S. True, *J. Am. Chem. Soc.*, 1984, **106**, 2451)

were studied over a less extensive pressure range, typically from a few torr to 5 atm. For the simplest amide studied, *N,N*-dimethylformamide, the ^1H dimethylamino resonances are magnetically equivalent in the gas phase, and exchange broadened ^{13}C NMR spectra were used to obtain rate constants.²⁸ Figure 3 shows ^{13}C gas phase NMR spectra of *N,N*-dimethylformamide as a function of temperature. For all the amides studied, Gibbs activation energies, $\Delta G^\ddagger$ are 5–10 kJ mol⁻¹ lower in the gas phase than in solutions for the same molecule. In solutions, the additional energy required to move solvent molecules when the dialkylamino group rotates partially explains the observations. Recent Monte Carlo simulations of solvent effects on the internal rotation barrier of *N,N*-dimethylacetamide, however, were not able to reproduce the observed phase dependent differences in activation parameters.³³

For cyclohexane and seven other six-membered rings which have been studied in the unimolecular pressure region, much smaller differences between gas and solution phase activation parameters were observed.^{34–41} NMR studies of cyclohexane demonstrated that gas phase rate constants are lower and activation parameters are higher than in the liquid phase. Early liquid phase studies at atmospheric pressure reported an activation energy of 42.7 ± 0.8 kJ mol⁻¹.³⁴ Recently, Jonas et al. have shown that measurements at constant sample viscosity produce a significantly higher activation energy, 47.2 ± 0.1 kJ mol⁻¹, which is much closer to the gas phase value, 52.5 ± 1.0 kJ mol⁻¹, obtained at 2500 torr.²⁵

Pressure dependent rate constants of unimolecular processes provide a test of kinetic theories. Statistical kinetic theories such as RRKM theory assume that the rate constant for intramolecular energy redistribution (IVR), k_{ivr} , in critically

energized molecules is rapid compared with the energy dependent reaction rate constant, $k(E)$ and that IVR is ergodic. According to the Fermi golden rule, k_{IVR} , is directly proportional to the density of states $\rho(E)$. Since $k(E)$ is inversely proportional to $\rho(E)$, the condition $k_{\text{IVR}} \gg k(E)$ is most likely to be valid at high state densities, and statistical theories of chemical reactions are therefore most applicable to large molecules undergoing processes at high activation energies. At the low activation energies required for conformational processes, critically energized molecules have sparse state densities and the anharmonic coupling constants among vibrational states are small. Under these conditions, statistical kinetic theories may not provide an adequate description of these processes. A qualitative indication of the applicability of statistical kinetic theories to conformational processes can be obtained by comparing the general shape and location of the falloff curve calculated with RRKM theory with pressure dependent rate constants obtained from NMR experiments. Experimental studies so far have been limited to a rather narrow pressure range. Recent work has shown that fall-off curves over an extended pressure range obtained with as high a definition as possible can provide a more critical test of intramolecular dynamics.

Pressure dependent chemical exchange rate constants over limited pressure ranges typically between a few torr and 4–5 atm have been obtained for larger nitrites,^{42–44} six-membered rings,^{34–39} SF_4 ,⁴⁵ bullvalene,⁴⁶ and aziridine.⁴⁷ All these molecules, with the exception of aziridine, undergo processes with activation energies below 55 kJ mol^{-1} . For dialkyl amides which have activation energies above 70 kJ mol^{-1} , rate constants are independent of pressure at pressures between a few torr and several atmospheres, and the fall-off region, predicted to occur below a few torr, has not been observed experimentally.

Methyl nitrite was the first molecule for which pressure dependent gas phase NMR spectra were obtained.⁴² Figure 4 shows recently obtained experimental and calculated rate constants for the *syn* $\rightleftharpoons$ *anti* exchange process of methyl nitrite. The solid line represents rate constants calculated using RRKM theory and the data points were obtained by analyzing exchange broadened lineshapes. The location of the fall-off is sensitive to the cross section for deactivating collisions, and a value of 0.3 nm adequately reproduces the location of the fall-off. The shape of the experimental and calculated curves are different, and the values of the parameters used in the RRKM calculation cannot be adjusted reasonably to reproduce the experimentally determined curvature.

Less extensive pressure dependent data are available for larger alkyl nitrites,^{42–44} six-membered rings,^{34–39} SF_4 ,⁴⁵ bullvalene,⁴⁶ and aziridine.⁴⁷ Comparisons of the location and shape of the fall-off curves for these molecules with RRKM theory have been made. The location of the fall-off curve depends strongly on the cross section for deactivating collisions, a parameter which has not been determined independently for any of these processes. Because of this uncertainty and additional uncertainties in the model parameters used in these calculations, and the experimental uncertainties in the shapes of the fall-off curves which have been obtained to date, only qualitative conclusions can be drawn from these studies. Acceptable agreement of observed and calculated fall-off curves is obtained for the larger nitrites^{43,44} and six-membered

Figure 4 Pressure dependent rate constants (k/k_∞) for the *syn*–*anti* conformer exchange process of methyl nitrite gas. The solid line represents RRKM calculated rate constants

rings.^{37–41} Molecules with lower state densities at the threshold energy such as SF_4 ,⁴⁵ aziridine,⁴⁷ and, possibly, methyl nitrite⁴² and cyclohexane³⁴ show less satisfactory agreement.

Rate constants in the low-pressure bimolecular region depend on the rate of activating collisions and are dependent on the nature of the collider. Bath gas relative collision efficiencies, β , for activating the methyl nitrite conformational conversion and the ring inversion of cyclohexane were determined by measuring rate constants as a function of bath gas pressure in the bimolecular region using ^1H NMR spectroscopy. For methyl nitrite *syn* $\rightleftharpoons$ *anti* conformer exchange, β correlates strongly ($R > 0.9$) with polarizability, indicating that the attractive portion of the intermolecular potential is important in determining collision efficiency.⁴⁸ For ring inversion in nonpolar cyclohexane there is no correlation between β and polarizability for the five noble gases studied, while β correlates positively with polarizability for homonuclear diatomics. The observed β values of the larger polyatomic molecules correlate strongly with polarizability, showing a greater dependence than the diatomic molecules. These results suggest that for monatomic gases colliding with cyclohexane the attractive portion of the intermolecular potential is not the dominant factor in collisional energy transfer. As the molecular complexity of the bath gas increases, it appears to play a more important role.⁴⁹

1 INTRODUCTION

In order to elucidate the mechanisms of chemical reactions, the kineticist studies the dependence of the reaction rate on a number of parameters, both chemical (reactant concentrations, pH, ionic strength, and solvent composition) and physical (normally temperature). The empirical rate law, the electronic and steric effects induced by changing the reactants, the variable temperature activation parameters (activation enthalpy, $\Delta H^\ddagger$ and activation entropy, $\Delta S^\ddagger$), and any other experimental or theoretical information available on the system are then used to assign a reaction mechanism. Such information may, however, be insufficient to distinguish clearly between alternative reaction mechanisms. Temperature is, however, not the only physical variable that can be varied in kinetic studies. Pressure can also affect the rate of a substitution reaction in solution, and variable pressure measurements yield an activation volume, $\Delta V^\ddagger$, which is now widely used as a supplementary (and often decisive) parameter for mechanistic assignment.¹ Although the first high pressure kinetic study in inorganic chemistry was made over 30 years ago, the rapid development of the field has occurred in the last 20 years, since the adaptation for variable pressure studies of most fast reaction techniques: stopped flow, temperature jump, pressure jump, and, especially, NMR. This is illustrated by the number of recent reviews in the field, of which the reader is referred to the most recent.²⁻⁴

The pressure dependence of the rate of a chemical reaction is usually described by transition state theory. The activation volume, the difference between the partial molar volumes of the transition state and the reactants, at a temperature T is defined by

$$(\partial \ln k / \partial P)_T = -\Delta V^\ddagger / RT \quad (1)$$

where k is the rate constant. The activation volume may itself depend on pressure, and it is useful to define the compressibility coefficient of activation, $\Delta\beta^\ddagger$, as

$$\Delta\beta^\ddagger = -(\partial \Delta V^\ddagger / \partial P)_T \quad (2)$$

It is usual to assume that $(\partial^2 \Delta V^\ddagger / \partial P^2)_T = 0$, so that $\ln k$ has the quadratic form

$$\ln k = \ln k_0 - P \Delta V_0^\ddagger / RT + P^2 \Delta\beta^\ddagger / 2RT \quad (3)$$

where $\Delta V_0^\ddagger$ is the activation volume at zero pressure. It should be stressed that there is no physical justification for such a quadratic form. On the other hand, $\ln k$ is often found empirically to be approximately linear in pressure, and a simplified form of equation (3) with $\Delta\beta^\ddagger = 0$ may be preferred.

Variable pressure NMR has most often been applied to ligand substitutions on metal ions as shown in equation (4), where X is the leaving ligand, Y the entering ligand, and L the nonreacting ligands on a metal M. The measured activation volume for such reactions is usually considered to be the sum of an intrinsic contribution, $\Delta V_{\text{int}}^\ddagger$, due to changes in internuclear distances within the reactants on formation of the transition state and a solvent electrostrictive contribution, $\Delta V_{\text{elec}}^\ddagger$. For substitution reactions involving charged species, $\Delta V^\ddagger$ may be dominated by $\Delta V_{\text{elec}}^\ddagger$, so that the sign of $\Delta V^\ddagger$ may be different from $\Delta V_{\text{int}}^\ddagger$. The power of the activation volume as a mechanistic indicator is particularly well illustrated by solvent exchange reactions [$X = Y$ in equation (4)], which are of fundamental importance to all substitution reactions in inorganic chemistry. In this case, one cannot easily vary the concentrations of the reactants so that the mechanistic assignment must often be made on the basis of activation parameters alone. For these reactions there is no significant charge or dipole formation on going to the transition state, so that $\Delta V_{\text{elec}}^\ddagger$ may be neglected. The sign of $\Delta V^\ddagger \approx \Delta V_{\text{int}}^\ddagger$ is then an immediate diagnostic of the activation step: dominant bond breaking results in a positive $\Delta V^\ddagger$ while dominant bond making gives a negative $\Delta V^\ddagger$.

The classification of substitution reaction mechanisms originally proposed by Langford and Gray,⁵ and widely used in coordination chemistry, is based on operational criteria. If kinetic tests show the presence of an intermediate of increased coordination number, an associative mechanism, A, is assigned. Conversely, if an intermediate of reduced coordination number is detected, a dissociative, D, mechanism is assigned. When no intermediate can be found, a concerted interchange, I, mechanism is assigned. This last category may be subdivided further, depending whether evidence is found for important incoming group influences (I_a) or not (I_d). Swaddle⁶ has argued that this operational definition is too restrictive, and may be extended to include activation parameters as operational criteria. This is especially true for solvent exchange reactions, where few kinetic tests are applicable. The activation volume is of primary importance in this context. Microscopic reversibility for solvent exchange reactions means that the forward reaction path must be symmetrical to the reverse one. For an interchange process, with no true minimum along the reaction coordinate, the bond lengths to the entering and leaving solvent molecules must be equivalent at the transition state. Thus, for an I_a mechanism, the incoming and outgoing solvent molecules will both have relatively strong bonds, whereas for an I_d mechanism they will have relatively weak bonds. The difference between the two mechanisms will be manifested as a contraction or expansion at the transition state. If the bond distances between the central ion and nonexchanging solvent molecules are unaltered, $\Delta V^\ddagger$ will be a direct measure of the degree of associativity or dissociativity

Figure 1 Volume profiles for solvent exchange mechanisms. (Reproduced by permission of Reidel from A. E. Merbach, in *High Pressure Chemistry and Biochemistry*, ed. R. van Eldik, 1987)

at the transition state. A continuous spectrum of transition states can thus be envisaged (Figure 1), ranging from limiting associative, A, with $\Delta V^\ddagger = -|\Delta V_{\text{lim}}^\ddagger|$, via I_a and I_d to limiting dissociative, D, with $\Delta V^\ddagger = +|\Delta V_{\text{lim}}^\ddagger|$. For interchange mechanisms characterized by $\Delta V^\ddagger \approx 0$, the activation mode cannot be specified, and no subscript is assigned to the I mechanism.

We have established the primary importance of $\Delta V^\ddagger$, and hence of variable pressure kinetic measurements, for the classification of reaction mechanisms. In Section 2 we will discuss the different approaches used to perform NMR measurements on liquids at high pressures. The rates of chemical reactions cover an enormous range of timescales: for example, water exchange rates at 298 K on metal cations vary from 10^{-8} s^{-1} for Rh^{3+} to almost 10^{10} s^{-1} for Cu^{2+} . A large battery of NMR techniques must be called on, therefore, to study these reactions. In Section 3 we draw on our work in Lausanne to illustrate some of the different techniques that are used and the importance of the activation volume in specific cases. Finally, in Section 4, we will give a brief review of the areas of chemical kinetics where high-pressure NMR has been applied, by our group and various others. In this section, we will give references only when the examples are drawn from recent research papers, otherwise the original references can be found in the aforementioned reviews.

2 HIGH-PRESSURE NMR INSTRUMENTATION AND METHODOLOGY

Two approaches have emerged for the measurement of NMR spectra at high pressure.^{7,8} The simplest approach is to design a pressurizable thick-walled glass sample tube which can be placed directly in a standard spectrometer probe. Such systems work well, and sample spinning can be used, but there are certain disadvantages. If small pressure dependences (e.g. activation volumes) are to be measured with any precision, pressures of at least 1 kbar are required. This can be achieved with very thick-walled tubes where the sample is confined to a capillary, but the poor filling factor of these tubes results in low

sensitivity. Furthermore, the temperature control of such tubes is not very good, and it cannot be emphasized too strongly that temperature has to be known as accurately as possible if the results of kinetic variable pressure measurements are to be meaningful.

The alternative approach is to manufacture a dedicated high-pressure probehead which will replace the ambient pressure commercial probehead. The probe is built around a high-pressure chamber provided with electrical lead-through contacts so that both the coil and sample are immersed in the high-pressure transmitting fluid. The coil can be wound on a support placed closely around the sample tube and so have a high filling factor. The pressure fluid is also a good heat transfer medium, and its heat capacity and that of the metallic bomb are such that temperature control can be more precise than is possible with the normal gas flow-type unit. The sample cannot be made to spin, or at least there are practical difficulties which preclude this, but using field lock and small diameter tubes (5 mm), good resolution can be obtained from the static sample. The signal-to-noise ratio does not suffer too much from this approach because of the good filling factor, and cryomagnets are capable of producing a remarkable magnetic field homogeneity over small volumes. In practice the static, specially built system has proved superior to the spinning pressure tube in all the factors outlined above, and especially for chemical kinetic studies.

For illustration we present a probe designed for a high-field spectrometer (Bruker AM-400).⁹ Figure 2(a) is a schematic drawing of a probehead designed for a wide bore (87 mm diameter) superconducting magnet (9.4 T), which can be used up to 200 MPa and is made of a nonmagnetic beryllium–copper alloy. Three connectors are located at the bottom: one for the pressure transmitting liquid, and two for the inlet and outlet of the thermostating liquid. An upper aluminum support (not shown in Figure 3) contains the high-frequency cables, screwdrivers for the adjustment of the matching/tuning capacitors and the frequency adapter box. The adapter box contains a capacitive matching/tuning network that

Figure 2 Schematic drawing of (a) a wide bore superconducting magnet multinuclear high-pressure bomb and (b) the internal component of the bomb made of Vespel (top) and the sample tube (bottom). (Reproduced by permission of Gordon and Breach from Frey et al.⁹)

Figure 3 Observed and calculated 60 MHz ^1H NMR spectra of a solution of $\text{M}(\text{TMPA})_6(\text{ClO}_4)_3$ dissolved in a mixture of TMPA and CD_3NO_2 , recorded as a function of pressure. The top spectra are for $\text{M} = \text{In}$ and the bottom spectra are for $\text{M} = \text{Al}$. (Reproduced by permission of Pergamon Press from Merbach¹⁰)

is specific for a small frequency range and so must be changed in order to observe different nuclei. Provision is made for the use of a ^2H lock.

The internal components of the bomb and the sample tube are shown in Figure 2(b). The radiofrequency coil is wound in a saddle shaped form on 7 mm o.d. glass tubing to produce a radiofrequency field perpendicular to the vertical static magnetic field. The temperature is measured inside the bomb by a platinum resistor placed just above the sample tube. The temperature stability is better than ± 0.2 K and is not a limiting factor in the accuracy of measurements of activation volumes. The sample tube is a 5 mm o.d. NMR tube cut to the right length and closed with a movable seal, made of machinable glass, which allows pressure transmission to the sample. The sample tube was designed to minimize the volume (1 cm^3) to economize on expensive solvents such as ^{17}O enriched water. The surrounding pressure transmitting liquid is chosen so as not to contain the observed nucleus. The spectral resolution and magnetic field stability with this nonspinning high-pressure probe is better than 0.5 Hz at 400 MHz and routinely better than 1 Hz.

3 EXAMPLES OF VARIABLE PRESSURE KINETIC STUDIES

3.1 TMPA Exchange on Aluminum(III) and Indium(III)¹⁰

Here we describe the use of proton NMR to observe the way TMPA exchanges on two related metal ions, both of which

form octahedral solvates with this ligand: $[\text{M}(\text{TMPA})_6]^{3+}$, with $\text{M} = \text{Al}$ and In . The ^1H spectrum of TMPA is a doublet due to spin–spin coupling to the phosphorus atom, and this doublet is maintained when the phosphate is complexed by a cation though it is shifted to high frequency. The spectrum of a solution of $[\text{M}(\text{TMPA})_6]^{3+}$ with excess TMPA, using deuterated nitromethane (CD_3NO_2) as a diluent, is thus two doublets, provided exchange is sufficiently slow. Exchange between free and bound solvent will cause line broadening and eventual collapse of the doublets.

The use of an inert diluent gives reduced viscosity leading to better resolution and definition of the linewidths and also permits the free ligand concentration to be varied so that information can be obtained regarding the order of reaction. For TMPA exchange on Al^{3+} this is first order while for In^{3+} it is second order. The entropies of activation also have opposite signs so that the ambient pressure data indicate strongly that the activation mode for TMPA exchange is dissociative on Al^{3+} and associative on In^{3+} . The variable pressure kinetics (Figure 3) provide a very good visual proof that the mechanisms are indeed different. The ^1H NMR spectrum for the TMPA exchange on In^{3+} at ambient pressure shows a doublet at low frequency which is due to free TMPA and a doublet at high frequency due to the six TMPA molecules coordinated to In^{3+} . With increasing pressure, at constant temperature, one observes a coalescence of the signals. This means that the exchange rate is increasing and therefore the activation volume will be negative ($\Delta V^\ddagger = -21.4 \text{ cm}^3 \text{ mol}^{-1}$). For $[\text{Al}(\text{TMPA})_6]^{3+}$ the change in spectra with pressure is the contrary: the deceleration of the ligand exchange with pressure indicates a positive activation volume ($\Delta V^\ddagger = +22.5 \text{ cm}^3 \text{ mol}^{-1}$). The difference in mechanistic behavior can be explained in terms of ionic radii. The large In^{3+} cation ($r_i = 80 \text{ pm}$) can easily accommodate, at least partially, a seventh solvent molecule in forming the activated complex. The small Al^{3+} ion ($r_i = 54 \text{ pm}$), on the other hand, is rather crowded, and has to expel a solvent molecule from the first coordination sphere at the transition state, before a new molecule can be accepted.

3.2 Water Exchange on the Lanthanide(III) Aqua Ions^{11–14}

We now turn to aqueous solutions of the paramagnetic lanthanides, where the bound solvent signal is too broad to be observed and where the influence of the paramagnetic ion on the bulk solvent relaxation is given by the Swift and Connick equations (see *Paramagnetic Relaxation in Solution*). Water exchange on the lanthanide(III) aqua ions is sufficiently rapid that the ^{17}O relaxation rates of aqueous lanthanide(III) perchlorate solutions are always in the fast exchange limit. In addition, for the paramagnetic lanthanide(III) ions Ce^{3+} to Yb^{3+} (except Gd^{3+}), the bound water relaxation is in the extreme narrowing limit, allowing one to use the approximate equation

$$\frac{1}{P_m} \left[\frac{1}{T_2} - \frac{1}{T_1} \right] = \frac{\Delta\omega_m^2}{k_{\text{ex}}} \quad (5)$$

where P_m is the mole fraction of bound water. $\Delta\omega_m$, the difference in chemical shift between the bound water and the

bulk water (in the absence of paramagnetic interaction with the bulk water), can be determined from the chemical shift of the paramagnetic solution compared with a nonparamagnetic reference solution. Measurement of the longitudinal and transverse ^{17}O relaxation rates, $1/T_1$ and $1/T_2$, in the paramagnetic solution therefore allows the water exchange rate, k_{ex} , to be determined.

For the series Tb^{3+} to Yb^{3+} the relaxation rate difference, $1/T_2 - 1/T_1$, was observed at 4.7 T and 8.5 T to be proportional to the square of the magnetic field, confirming the approximations used in equation (5), and reliable parameters were obtained for this series. For the lighter lanthanides, Nd^{3+} and Eu^{3+} , the bound water chemical shift, $\Delta\omega_{\text{m}}$, was too small for the relaxation rate difference in equation (5) to be measurable. Variable pressure ^{17}O relaxation rate measurements were made in a high-pressure probe at 9.4 T.

As mentioned above, Gd^{3+} is a case apart. The relatively slow electronic relaxation rates lead to breakdown of the extreme narrowing approximation for bound water relaxation, and equation (5) cannot be used. In order to determine k_{ex} it is necessary to consider the microscopic origins of the relaxation of the bound water. The transverse ^{17}O relaxation rate in bound water, $1/T_{2\text{m}}$, is dominated by relaxation due to the scalar or contact interaction originating from the finite Gd^{3+} electron spin density at the ^{17}O nucleus and given in approximate form by

$$\frac{1}{T_{2\text{m}}} = \frac{1}{P_{\text{m}}} \left[\frac{1}{T_2} - \frac{1}{T_{2\text{A}}} \right] = \frac{S(S+1)}{3} \left(\frac{A}{\hbar} \right)^2 \left[k_{\text{ex}} + \frac{1}{T_{1\text{e}}} \right]^{-1} \quad (6)$$

where $1/T_{2\text{A}}$ is the transverse relaxation rate in the nonparamagnetic reference, $S = \frac{7}{2}$ is the Gd^{3+} electron spin, and $1/T_{1\text{e}}$ is the longitudinal electronic relaxation rate. The scalar coupling constant, $A/\hbar$, is accessible from the chemical shift. Thus, ^{17}O NMR relaxation rate measurements allow one to determine k_{ex} , provided that $1/T_{1\text{e}}$ is known. It is therefore necessary to also make ESR measurements: the ESR linewidth is directly proportional to the transverse electronic relaxation rate, $1/T_{2\text{e}}$, which can be related to $1/T_{1\text{e}}$ using a theoretical model.

A combined ^{17}O NMR and EPR study of the Gd^{3+} aqua ion was first made in 1980, and has recently been improved by extension to a greater number of ESR and NMR magnetic fields. The calculated contribution of $1/T_{1\text{e}}$ to $1/T_{2\text{m}}$ decreases to less than 3% at 9.4 T, so that k_{ex} and the temperature and pressure activation parameters are determined well from these high-field measurements.

The water exchange parameters for the lanthanide(III) aqua ions Gd^{3+} to Yb^{3+} are shown in Figure 4. The water exchange rates decrease as one progresses along the series, as one might expect for a dissociative process (the energy required to remove a water molecule increasing with the lanthanide ion charge density). The negative $\Delta V^\ddagger$, however, clearly indicate an associatively activated exchange mechanism. The coordination number of the lanthanide aqua ions is known from neutron diffraction experiments to change from nine for the larger aqua ions on the left of the series to eight for the smaller aqua ions on the right of the series. This coordination number change is manifested in the measured absolute partial molar volumes of the ions shown in Figure 4, which approach the calculated values for the ennea and octa aqua species for the lighter and heavier lanthanides respectively. The

Figure 4 Absolute partial molar volumes, V_{abs} , of the Ln^{3+} aqua ions in LnCl_3 solutions, compared with calculated values for the octa and ennea aqua ions. $\square$, interchange rate constants, k_1^{298} (s^{-1}), for complexation of the Ln^{3+} aqua ions with SO_4^{2-} ; $\bullet$, water exchange rates, k_{ex}^{298} (s^{-1}), and the corresponding activation volumes ($\blacksquare$) for the Ln^{3+} aqua ions

water exchange mechanism on the lanthanide aqua ions can, therefore, be understood in terms of the reaction in equation (7). For the heavy lanthanides, the octa ion is the lowest energy species, and the ennea aqua ion is the intermediate (or transition state) in the associatively activated water exchange reaction. The activation volumes are, therefore, negative, and the water exchange rates increase toward the middle of the series, as less energy is required to reach the ennea aqua transition state. For the light lanthanides the ennea aqua ion is now the lowest energy species. One can expect, therefore, that the octa aqua ion will be the intermediate (or transition state) in the exchange process, which will proceed via a dissociative, D, or dissociative interchange, I_{d} , mechanism. For the mid-series lanthanides (Pm^{3+} to Eu^{3+} according to Figure 4), the octa and ennea aqua species are in equilibrium. The transition from one species to the other requires relatively little energy, so that these lanthanides should have the fastest water exchange rates for the series. This interpretation is supported by results from studies of complex formation on the lanthanide(III) aqua ions. The interchange rate, k_1^{298} (s^{-1}), of an inner sphere water molecule by a SO_4^{2-} ion already in an outer sphere complex is shown in Figure 4. The values are closely correlated with the rate of water exchange, and show a maximum in the middle of the series, which corresponds to the cross over in the absolute partial molar volumes of the aqua ions. If one could measure the water exchange rates on the light lanthanide ions, Ln^{3+} to Nd^{3+} (e.g. by using the very high NMR fields now available) one would, therefore, expect positive activation volumes for these aqua ions, and water exchange rates that decrease as one moves away from the middle of the series and more energy is

needed to reach the octa aqua transition state.

3.3 TMPA Exchange on

Tetrachlorobis(TMPA)zirconium(IV)¹⁵

The system discussed here involves a much more complex ligand exchange process. The two ligands, L, in $\text{ZrCl}_4 \cdot 2\text{L}$ can be either *cis* or *trans* with respect to one another so that there are three possible exchange reactions given by equations (8)–(10).

At 236 K, the ^1H NMR spectrum of a solution of $\text{ZrCl}_4 \cdot 2\text{TMPA}$ in chloroform with excess TMPA consists of three doublets due to the two forms of the complex and the free ligand, with $^3J(^{31}\text{P}, ^1\text{H}) = 14.0\text{ Hz}$ for the latter and 11.7 and 11.8 Hz in the *cis* and *trans* complexes, respectively. As the temperature is raised, the doublets of the *cis* and *trans* isomers broaden and eventually coalesce, indicating that the *cis/trans* isomerization reaction occurs first. At a slightly higher temperature, the doublet of the free ligand also broadens and coalesces with the signal of the *cis/trans* isomers. The source of this second broadening could be due to a ligand exchange reaction between free ligand and the *cis* and/or *trans* isomer. In this case, NMR line-broadening simulation cannot easily be used to quantify the individual contribution of the three exchange reactions to the observed spectra.

It has now been shown that this problem can be overcome by using the very powerful 2D NMR techniques. In the moderately slow exchange region where all the signals can be observed, a pulse sequence that is sensitive to exchange effects gives off-diagonal peaks where there is an exchange reaction. So, all the signals can be examined for exchange coupling and the individual exchange rate can be obtained. In addition, if a high-pressure probe is available for a suitable spectrometer, then it is possible to carry out a variable pressure 2D experiment without too much difficulty.

Proton (400 MHz) EXSY spectra were recorded on a Bruker AM-400 spectrometer equipped with a home built high-pressure probe, using the pulse sequence $90^\circ(\Phi_1)-t_1-90^\circ(\Phi_2)-\tau_m-90^\circ(\Phi_3)-t_2$. A double Fourier transformation with respect to t_1 and t_2 gives a rectangular stacked spectrum plot (Figure 5) with the resonances of the normal spectrum displayed on a diagonal and any exchange is manifested by off-diagonal peaks at the intersection of the chemical shifts of the connected peaks in the two frequency directions. The relative intensities of the cross peaks is related to the relative rates of exchange and so these can be measured for all pathways and changes in both relative and absolute rates with pressure can be measured.

The length of the diagonal in Figure 5 is 0.50 ppm, and the doublet due to free ligand is at low frequency, to the right

Figure 5 (400 MHz) 2D Proton EXSY spectra of *cis*- and *trans*- $\text{ZrCl}_4 \cdot 2\text{TMPA}$ in the presence of excess TMPA, at two different pressures [(a) 0.1 MPa, (b) 198 MPa] demonstrating the effect of pressure on the intramolecular and intermolecular exchange pathways. (Reproduced by permission of Elsevier from Frey et al.¹⁵)

of the plot. The doublet at the extreme opposite end of the diagonal is due to the *trans* isomer and the doublet of the *cis* isomer can be discerned a little to low frequency. At ambient pressure there are strong off-diagonal peaks connecting the resonances of the *cis* and *trans* isomers as would be expected (see above). Weaker off-diagonal peaks connect the free ligand with the *trans* isomer, and those connecting free ligand with the *cis* isomer are just discernible. An increase in the pressure produces a small increase in intensity of the off-diagonal peaks due to the *cis/trans* isomerisation reaction. This isomerization, with a small negative activation volume ($\Delta V_i^\ddagger = -1.6 \pm 0.6\text{ cm}^3\text{ mol}^{-1}$), is intramolecular and proceeds via a slightly contracted six-coordinate transition state. On the other hand, the intensities of the off-diagonal peaks due to the intermolecular ligand exchange on both *cis* and *trans* isomers increase strongly with pressure ($\Delta V_i^\ddagger = -11.1 \pm 0.8\text{ cm}^3\text{ mol}^{-1}$), showing that the ligand exchange reactions are both associative. This is in marked contrast to the similar reactions occurring with the analog with the smaller Ti^{4+} ion ($\Delta V_i^\ddagger = +17.5\text{ cm}^3\text{ mol}^{-1}$). Given that the reaction of the *trans* complex predominates, it is then possible to obtain activation parameters in the normal way and show, by changing the free ligand concentration, that the ligand exchange is second order, as required for an associative process.

4 FIELDS OF APPLICATION OF HIGH-PRESSURE NMR IN CHEMICAL KINETICS

4.1 Substitution Reactions and Solvent Exchange

The substitution reactions that have been most extensively studied by NMR are the solvent exchange reactions on divalent and trivalent first row transition metal ions. The measured activation volumes shown in Tables 1 and 2 clearly show a progressive change of activation mode from associative for the early elements to dissociative for the late elements. This change can be explained by the combined effect of the progressive filling of the d orbitals and the decrease in ionic radii across the series, both of which disfavor bonding processes. The only case where the mechanistic changeover is not clear cut is dimethylformamide (DMF) exchange on the divalent ions: the activation volumes are all positive, although very small for Mn^{2+} . This is presumably due to the relative bulkiness of DMF favoring a dissociative activation mode.

The effect of the size of the solvent molecules can be seen very clearly in studies of solvent exchange on tetravalently coordinated Be^{2+} . The measured activation volumes and assigned mechanisms are shown in Table 3. Solvent exchange takes place via associatively activated mechanisms (A or I_a) for H_2O , dimethyl sulfoxide (DMSO), and TMPA, but the greater bulk of the TMU and DMPU ligands prevents the incoming solvent molecule from entering the coordination sphere before the outgoing solvent molecule leaves, and the exchange mechanism is dissociative, D.

Another factor in determining solvent exchange mechanism is the effect of multidentate ligands on the exchange of remaining solvent molecules. This has been shown to be especially important for Gd^{3+} polyaminocarboxylates,

where the rate of water exchange is important for their use as contrast agents in medical magnetic resonance imaging. Kinetic parameters for the Gd^{3+} octa aqua ion and the complexes with propylenediaminetetraacetate (PDTA^{4-}),¹⁴ diethylenetriaminepentaacetate (DTPA^{5-}),¹⁶ tetraazacyclododecanetetraacetate (DOTA^{4-}),¹⁶ and diethylenetriaminepentaacetate bismethylamide (DTPA-BMA^{3-})¹⁷ are shown in Table 4. The exchange rates on the three contrast agents, $[\text{Gd}(\text{DTPA})(\text{H}_2\text{O})]^{2-}$, $[\text{Gd}(\text{DOTA})(\text{H}_2\text{O})]^-$, and $[\text{Gd}(\text{DTPA-BMA})(\text{H}_2\text{O})]$, are 200–2000 times lower than on the octa aqua ion. This rate decrease is accompanied by a change of sign of the activation volume, the large positive values for the three contrast agents indicating dissociatively, rather than associatively, activated water exchange. This is a consequence of the change of coordination number to nine for the contrast agents, which prevents the entry of a second water molecule into the coordination sphere. Without the participation of the incoming water molecule, more energy is required to break the bond between the outgoing water molecule and the highly charged Gd^{3+} , leading to the higher activation enthalpies and lower water exchange rates.

4.2 Redox Reactions

The effect of pressure on the classic outer sphere electron transfer reaction between the aqueous anions MnO_4^{2-} and MnO_4^- has been investigated by ^{55}Mn NMR line broadening. The reaction proceeds by two pathways: in one the cation facilitates the approach of the two anions whereas in the other the reaction is cation independent. The first pathway has a rather small activation volume, but for the second $\Delta V^\ddagger \approx -21 \text{ cm}^3 \text{ mol}^{-1}$. This can be accommodated with current theory if it is assumed that the Mn–Mn distance in the

tyrosine (Tyr35)] buried in the interior of the basic pancreatic trypsin inhibitor were studied by ¹H NMR. The interior of this globular protein is quite compact, implying that internal fluctuations of the protein backbone are necessary in order to permit reorientation within the residues. The motion of the aromatic rings had a similar activation volume for the two residues: 30 cm³ mol⁻¹ for Phe45 and 36 cm³ mol⁻¹ for Tyr35. These volumes correspond reasonably with the difference between the volume of a ring and the smallest volume that it can be regarded as sweeping out as it rotates. Alternatively, it was suggested that since the region around a ring contains a significant proportion of void space among the atoms hindering

transition state ion pair is reduced as the pressure is increased, at a rate that allows the solvent cavity in which the ion pair is contained to compress to the same extent as the solvent. The outer sphere electron transfer between $[\text{Mn}(\text{CNR})_6]^+$ and $[\text{Mn}(\text{CNR})_6]^{2+}$ has also been studied using ⁵⁵Mn NMR with R = CNBu^t and R = CNC₆H₁₁ and in a series of solvents. The activation volumes range from -9 to -22 cm³ mol⁻¹, and show evidence for ion pairing in the solvents of lower dielectric constant. The qualitative difference in the solvent dependence of the rate constant for R = CNBu^t and R = CNC₆H₁₁ is evidence for the significant influence of subtle differences in solvation on the molecular level that is not approximated by continuum models. Variable pressure NMR studies have also been made of electron transfer between the pairs Fe(II)/Fe(III), Cu(I)/Cu(II), and Ru(II)/Ru(III).

4.3 Spin Equilibria

Where Ni²⁺ is complexed by certain tetraaza macrocyclic ligands, an equilibrium exists between unsolvated planar diamagnetic and disolvated pseudooctahedral paramagnetic forms. The contact shift of the ligand protons can be used to measure the equilibrium between the forms, and a reaction volume for going from the planar to the pseudooctahedral form of -10.0 ± 0.1 cm³ mol⁻¹ was obtained in this way for the complex with the ligand 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane in aqueous solution. This volume is much less than the molar volume of the two molecules that enter the first coordination sphere (36 cm³ mol⁻¹). This is because the volume reduction is partially compensated by an expansion of the complex due to a change in the Ni-N distance on changing spin state.

4.4 Bioinorganic Chemistry

Variable pressure NMR has been used to study the kinetics of internal motions on proteins. For example, the reorientational motions of amino acid residues [phenylalanine (Phe45) and

rotation, quite small adjustments to the positions of these atoms will provide free space to permit ring rotation.

4.5 Organometallic Chemistry and Catalysis

The study of organometallic catalytic processes under gas pressure is of great interest despite the hazards involved in using compressed gases. A striking recent example is the catalytic dimerisation of ethylene in aqueous Ru²⁺ solutions, which was studied by ¹⁷O, ¹³C, and ¹H NMR in pressurizable sapphire NMR tubes.¹⁸ Three identical ¹⁷O enriched aqueous solutions of $[\text{Ru}(\text{H}_2\text{O})_6]^{2+}$ in 10 mm o.d. sapphire tubes were pressurized with ethylene at 6 MPa and mixed by shaking for different amounts of time. The NMR spectra showed the successive formation of $[\text{Ru}(\text{CH}_2=\text{CH}_2)(\text{H}_2\text{O})_5]^{2+}$ and $[\text{Ru}(\text{CH}_2=\text{CH}_2)_2(\text{H}_2\text{O})_4]^{2+}$. After shaking under ethylene pressure for 3 days, an organic phase formed above the solution. The ¹³C spectra of this new organic phase, separated under pressure, show characteristic signals of butenes. This aqueous catalytic dimerization reaction is not stereoselective, and all the possible butenes are formed except 2-methylpropene. These results show the utility of NMR studies under gas pressure for the study of catalytic reactions in aqueous solution, which are increasingly attractive with respect to ecological considerations.

There is also interest in the measurement of activation volumes for reactions and internal processes in organometallic compounds. For instance, the ring inversion of cyclic thio ligands in *trans*-PdBr₂(SCH₂CMe₂CH₂)₂ was studied under pressure. The activation volume was essentially zero, indicating no association, dissociation, or solvent participation in the inversion process. The exchange processes in a mixture of dimeric $[\text{Pd}(2\text{-methylallyl})\text{Cl}]_2$ and monomeric $\text{Pd}(2\text{-methylallyl})\text{Cl}(\text{PPh}_3)$ was also studied by variable pressure ¹H NMR. The activation volume depends on temperature, indicating a change of mechanism. At 22 °C, $\Delta V^\ddagger$ is essentially zero. The *syn-anti* exchange of the allyl hydrogen atoms occurs in the monomer, catalysed by association with

the dimer and the volume change due to this association is canceled by that due to cleavage of the dimer bridge. At 56 °C, $\Delta V^\ddagger = +11 \pm 2 \text{ cm}^3 \text{ mol}^{-1}$: methylallyl exchange now occurs by a process involving dimer cleavage followed by PPh_3 transfer, and it is the cleavage that produces the expansion.

4.6 Organic Chemistry

High-pressure NMR has been used to study a variety of reactions in organic chemistry. For instance, the volume profiles for the rearrangement of two norbornyl cations have been studied. For rearrangement of the 1,2-dimethoxy-2-norbornyl cation, $\Delta V^\ddagger = +8.7 \pm 0.5 \text{ cm}^3 \text{ mol}^{-1}$, expansion occurs because the transition state cation has a delocalized charge distribution that reduces interactions with the solvent. Rearrangement of the 7-methyl-7-norbornadienyl cation, on the other hand, takes place via an intermediate with increased charge localization, and one would expect a negative activation volume due to contraction around the transition state. In fact $\Delta V^\ddagger \approx 0$, and this is explained by a cancellation of the contraction by an expansion due to bond rupture during the rearrangement.

In the thermolysis of acetyl benzoyl peroxide it was found that pressure retards the rate of peroxide cleavage and increases the ratio of cage product to escape product. The data yield the activation volume for the initiator decomposition ($4 \text{ cm}^3 \text{ mol}^{-1}$) and the difference in activation volume for the formation of escape and cage products ($8 \text{ cm}^3 \text{ mol}^{-1}$). The effect of pressure on the rates of sigmatropic shifts in 5-(trimethylsilyl)cyclopentadiene, 5-formylpentamethylcyclopentadiene, and bullavene has also been observed. The activation volumes for the silyl compound are negative and depend strongly on solvent, indicating that considerable charge separation occurs in the transition state in chloroform solution, but much less in benzene. The activation volume is much smaller for the formyl compound, indicating that no charge separation occurs, at least in benzene–Freon.

Two reactions that comprise equilibrium addition of a protic species to a carbonyl group have been studied. In the first case, the intramolecular hydroketone–hemiacetal interconversion, $\Delta V^\ddagger = -3.2 \text{ cm}^3 \text{ mol}^{-1}$, is interpreted as being the volume change necessary for bond formation in this necessarily associative process. The second reaction, the intramolecular addition of thiol to acetyl cyanide, has $\Delta V^\ddagger = -13 \text{ cm}^3 \text{ mol}^{-1}$. This much larger value is believed to comprise the volume change necessary for bond formation plus the larger volume contraction that occurs upon the simple association of two molecules.

4.7 Silicates

The initial stages of the sol–gel condensation process that occurs following hydrolysis of $\text{Si}(\text{OMe})_4$ have been followed by variable pressure ^{29}Si NMR. Increased pressure increases markedly the rate of condensation without changing the mechanism, and it is possible that by carrying out such preparations at high pressure one can improve the properties of the glasses and ceramics that are the final objective of the process.

1 INTRODUCTION

Magnetic equivalence arises from symmetry. It is convenient to divide symmetry into two parts. The first is the point group symmetry of the molecule (or ion). The second is the symmetry that involves rapid intramolecular motions such as internal rotation of parts of the molecule against other parts, molecular inversion, or shifting of bonds between atoms in the molecule. As the temperature is lowered, these motions or rearrangements may slow down so much that nuclei (or sets of nuclei) that were equivalent at higher temperature become magnetically nonequivalent. (Magnetic equivalence that is achieved by interaction between molecules and/or intermolecular events is excluded from discussion in this article.)

Rapid processes are those by definition that occur with a frequency greater than the chemical shift difference between the NMR signals from the nuclei if they were nonequivalent. The spectrum that occurs at higher temperature when processes are rapid and the nuclei are equivalent is known as the *fast exchange spectrum*. The spectrum at lower temperature and when processes are slow is known as the *slow exchange spectrum*. The spectra at intermediate temperatures are said to be *intermediate exchange spectra*. Typically signals are broadened to become perhaps almost featureless humps for nuclei in the temperature region of intermediate exchange. Signal shape analysis of broadened signals can yield rate

data and kinetic parameters. The kinetic window for signal shape analysis can vary substantially for different situations. However, typically rates of $10\text{--}1000\text{ s}^{-1}$ can be determined by signal shape analysis. (The free energy of activation, $\Delta G^\ddagger$, as reported in the literature for various processes is quoted in this article. The temperature is always 298 K, unless otherwise noted.)

For convenience in discussion, point group symmetry will be referred to as *static symmetry*. The effect of internal motions will be referred to as *dynamic symmetry*. In fact, manifestation of dynamic symmetry is commonly called DNMR (dynamic NMR).

The operations of static symmetry and dynamic symmetry can be brought together to form a *permutation group* for the nuclei or groups of nuclei under discussion. This may seem strange since static symmetry depends only on geometry and does not actually move nuclei, while dynamic symmetry depends on actually moving nuclei. However, mathematically there is no qualitative distinction between the outcome of the two kinds of symmetry. In any event the nuclei are permuted (or in more common language they are exchanged). Permutation group theory is not discussed as such in this article, but it will be useful to use some of the ideas of permutation groups.

It is important to note that NMR of itself does not necessarily specify uniquely the dynamic physical process that permutes nuclei in any given case. It may, however, reveal which nuclei are exchanging with which nuclei. The detection of mutual exchange will be discussed in the main body of this article. But any analysis as to detailed mechanism requires additional information or theory outside the NMR experiment. However, a knowledge of mutual exchange may rule out certain mechanisms from a list of otherwise plausible mechanisms.

In spite of this caveat as to the limits of mechanistic information from NMR alone, the main article is organized to some extent around demonstrations of rotation around bonds, molecular inversion, and other specific internal motions, shifting of bonds, or combinations of such as these. The choice of interpretation of the nuclear exchange has always been assisted by outside considerations, even though these considerations may not be explicitly stated in the discussion that follows.

Individual studies have been selected for discussion in this article to represent principles. There is no attempt to give a review-like coverage of the very large literature that is continuing to emerge on the subject. Selection has not been made on the basis of clear superiority of one report over similar reports. The literature is too large and choice too subjective to guarantee that the selection has been made entirely on the basis of merit or of scientific importance.

Finally, a large share of the literature covered in this article was published in the approximate period from 1960 to 1975. The principles that were established in that period are now almost a matter of routine, but of course with newly interesting manifestations. Section 16, General References, refers to a variety of reviews and literature collections and should be consulted for a much wider coverage of magnetic equivalence and dynamic NMR than was possible to give in composing the present article. Also the bulk of the NMR studies have been undertaken by proton NMR methods. Unless otherwise specified or obvious, NMR stands for proton NMR in this article.

2 A HYPOTHETICAL MOLECULE

Some of the discussion in the Introduction can be illustrated with simple examples. The first example deals with a hypothetical molecule (1). So long as the R^1 , R^2 , and R^3 groups are all different, the carbon atom, C^* , is asymmetric and the molecule has no symmetry plane. As a consequence, the hydrogen atoms, H_A and H_B , are nonequivalent since there is no static symmetry between them. Inversion of the asymmetric carbon atom would be a dynamic symmetry operation, but inversion of such a carbon atom is much too slow by many orders of magnitude to be an effective dynamic symmetry operation.

It might be supposed that rotation around the bond between the carbon atoms could constitute a dynamic symmetry operation, but this is not correct. Rapid rotation around that bond might tend to average out the environments of the hydrogen atoms, but the averaging could never be complete. It is suggested here that this last point is best demonstrated by experimenting with molecular models. On the other hand, if any two of the R^1 , R^2 , or R^3 groups were the same, there could be a symmetry plane between the hydrogen atoms. This static symmetry element would make the hydrogen atoms magnetically equivalent.

The usual twisting and turnings, rotations and vibrations of the rest of the molecule would ordinarily be much too rapid on the NMR timescale to destroy this equivalence. Variable temperature NMR studies are at the heart of much of the discussion of magnetic equivalence or the lack of it. If an internal rearrangement is so rapid that it cannot be 'frozen out' at the lowest experimentally attainable temperature, then it is just part of the background. It does not stand out as a dynamic symmetry operation, the effect of which is amenable to study by variable temperature NMR.

Given the asymmetric carbon atom, the hydrogen atoms are *diastereotopic*. This term will be used frequently in later discussions. In principle any geminal species can be diastereotopic. Isopropyl radicals are often included in molecules chosen for study. The methyl groups within an isopropyl group can be diastereotopic. Molecular inversion is the only dynamic operation that can render the methyl groups equivalent. If the methyl groups remain nonequivalent, then rapid inversion is not occurring. Of course other geminal pairs can serve the same purpose but their utility is usually lessened by the complex spectra that can occur, while methyl nonequivalence can lead to signal patterns that are easy to analyze, often at a glance.

3 DIMETHYLFORMAMIDE: INTERNAL ROTATION

The observation by Phillips¹ of the effect of temperature on the proton magnetic resonance spectrum of *N,N*-dimethylformamide and its explanation as internal rotation is one of the earliest records of intramolecular exchange in NMR.

The core framework of amides is planar. There is partial double bond character in the carbonyl-to-nitrogen bond (the amide bond). Pauling² calculated the resonance energy to be 88 kJ mol⁻¹. For present purposes, resonance energy and the partial double bond character are manifest as the barrier to rotation around the amide bond.

Phillips observed that there is only one methyl signal at the fast exchange limit, but that this signal splits into two methyl signals at the slow exchange limit. He explained this behavior as being due to rapid rotation around the amide bond at higher temperature with the rotation slowing down as the slow exchange limit is reached at lower temperature.

Gutowsky and Holm³ utilized the techniques of Gutowsky's earlier signal shape studies to determine the rate of rotation in dimethylformamide. They obtained a $\Delta G^\ddagger$ value of 92 kJ mol⁻¹. Since this pioneering work, there has been and continues to be a veritable torrent of applications to a large variety of intermolecular as well as intramolecular rate problems.

The symmetry considerations that are involved are straightforward. In the planar ground state, both methyl groups lie in the amide plane. Since there is no static symmetry element between the methyl groups, they are nonequivalent in the ground state. One methyl group is *cis* to the carbonyl oxygen and the other is *trans*. Rapid rotation around the amide bond is the dynamic symmetry operation that makes the methyl groups equivalent.

This set of symmetry considerations applies for amides in general and even more generally to rotation around the bond between trigonally bonded atoms in a variety of molecules that have a planar ground state. On the other hand, biphenyls, as examples, have the rotating parts in an out-of-plane ground state, and the barrier to rotation is substantially steric rather than electronic as it is in rotation around the amide bond.

4 BIPHENYL-LIKE ROTATION IN CERTAIN ANILIDES

Dynamic NMR of anilides with unsymmetrical substitution in the benzene ring demonstrates how a missing static symmetry operation can be replaced by a dynamic symmetry operation and magnetic equivalence is then achieved.

In ground state anilides of the general type (2) the benzene ring is perpendicular to the amide plane. If the ring is symmetrically substituted, the perpendicular plane through the ring is a symmetry plane (a static symmetry element). If both *ortho* substituents are not the same, this symmetry plane is lost, a chiral center is established, and the molecule becomes chiral. This situation was first reported by Adams and his students⁴ well before the advent of NMR in chemistry.

Figure 1 Double proton signals at 40 °C of an anilide dissolved in $\text{CHCl}_2\text{CHCl}_2$. [Reprinted with permission from Siddall and Stewart, *J. Phys. Chem.*, **73**, 40. Copyright (1969) American Chemical Society]

Rotation around the benzene-to-nitrogen bond is generally slow on the NMR timescale at room temperature, but becomes rapid at elevated temperature. Rapid rotation then becomes a dynamic symmetry operation and substitutes for the lost symmetry plane. (Generally, the *cis/trans* isomerism due to slow rotation around the carbonyl-to-nitrogen bond is not observed in anilides of this type except in formanilides. Probably this is due to the predominance of one geometric isomer over the other to the point of excluding the lesser isomer from observation.)

This situation is demonstrated in a striking manner if a second chiral center is introduced into the anilide molecule.⁵ With two chiral centers the molecule exists as two diastereoisomers. In the slow exchange limit each of the two isomers exhibits its own set of NMR signals. This in effect doubles the signals in the NMR spectrum as can be seen in Figure 1.

However, raising the temperature increases the rate of rotation around the benzene-to-nitrogen bond and the doubled signal sets coalesce into a single set of signals. The single signal is the average over the rapid equilibrium between the two isomers. Rapid rotation has substituted for the lost symmetry plane and leads to magnetic equivalence.

5 ROTATION OF METHYL GROUPS AS A DYNAMIC SYMMETRY OPERATION

The barrier to rotation of methyl groups is typically quite small, 12–13 kJ mol^{-1} . As a consequence, rotation of the methyl group is very rapid on the NMR timescale and is usually not explicitly considered as a dynamic symmetry operation in evaluating symmetry for NMR purposes. However, extreme crowding in 1-*t*-butyl-5,6,7,8-tetrachloro-1,4-dihydronaphthalene 1,4-endoxide (**3**) slows methyl group rotation down sufficiently to be detectable.⁶

At room temperature, the *t*-butyl group gave a sharp singlet. At $-60\text{ }^{\circ}\text{C}$, the methyl groups within the *t*-butyl group are nonequivalent and the original singlet becomes three sharp singlets. Rotation around the bond to the *t*-butyl group evidently has slowed down. As the temperature was lowered still further to $-121\text{ }^{\circ}\text{C}$ and finally to $-133\text{ }^{\circ}\text{C}$, two of the three methyl signals broadened almost to the point of decoalescence, while the singlet from the third methyl group remained little changed. Apparently the temperature could not be lowered sufficiently to give the slow exchange spectrum. The authors examined possibilities other than slow methyl rotation as explanations for the broadening, but were able to dismiss these other possible explanations.

6 GEARED ISOPROPYL GROUPS

Rapid rotation of isopropyl groups is usually automatically taken for granted as part of a big background of rapid internal molecular motions that are not singled out as dynamic symmetry operations, since they are rapid on the NMR timescale at accessible temperatures. However, there is considerable evidence that isopropyl rotation can be slow, especially if isopropyl groups are in close enough proximity to each other to interact sterically. This steric interaction apparently can take the form of synchronous rotation. Such isopropyl rotations have been quite aptly labeled as geared rotation⁷ or cogwheeling. Furthermore, the rotation of other groups that are adjacent to the geared isopropyl groups can

be slowed because of steric interactions with the isopropyl groups.

In the molecule described below, benzyl group rotation is slowed because of interaction with the isopropyl groups. (The NMR studies were made both with proton NMR and with carbon-13 NMR. The two spectroscopies substantiated each other in detail. This being the case and in the interest of economy in discussion, only the proton behavior is described below.)

The room temperature spectrum⁷ of 1,3-dibenzyl-4,5-diisopropyl-2-thione (**4a**, **4b**) is just as would be expected. At highest frequency, the benzene ring protons give a multiplet; moving to low frequency, the methylene protons give a singlet, then there is the methine septet, and finally at lowest frequency there is the expected methyl doublet. The static symmetry is C_{2v} . The molecule lies in one plane. The plane perpendicular to the molecular plane makes the isopropyl groups equivalent as whole groups and also the benzyl groups equivalent as whole groups. The molecular symmetry plane makes the protons within a methylene group equivalent and the methyl groups within an isopropyl group equivalent.

The spectrum at -112°C is anything but routine. The C_{2v} symmetry is destroyed. There are no longer any symmetry planes nor a C_2 axis. Methylene protons give four separate AB patterns and are clearly diastereotopic. The methine signals have disappeared into baseline noise, but there are four methyl doublets. The increase to four AB patterns definitely shows that there are four different low temperature environments for the methylene groups and eight environments for the methylene protons.

The existence of only four methyl doublets from the isopropyl groups might be unexpected. If there are eight environments for the methylene protons, eight environments would be expected for the methyl groups. This could lead to eight doublets rather than just four. Precise signal overlap to give just four pairs of doublets could be an explanation, but does require an uncomfortable degree of coincidence. However, since no alternative explanation is readily forthcoming, the discussion will be continued, while ignoring this difficulty, which is what the authors of the paper did.

The spectra taken between -20°C and -90°C indicate that more than one rate process is taking place. The process that is observed below -20°C is assigned to the synchronous rotation of the isopropyl groups. At lower temperature, the process of rotation around the bond of one of the benzyl groups is being slowed down. At still lower temperature, the rotation of the other benzyl group is slowing. The $\Delta G^{\ddagger}$ value was calculated to be 48 kJ mol^{-1} at 223.6 K for the isopropyl process, and 45 and 36 kJ mol^{-1} for the two different benzyl rotations.

The process shown below is central to rationalizing the spectral observations. The isopropyl groups, acting as gears, tend to lock into one or the other of two positions. The

positions are mirror images of each other. The gears rotate rapidly on the NMR timescale at room temperature. The gears lock and unlock so quickly that the locked positions average out. At about -20°C the lock–unlock rotation slows down to the slow exchange limit as far as the isopropyl rotations are concerned. Meanwhile, the rotamer lifetime of the benzyl groups is still very short, still at rapid exchange. Many benzyl rotations occur during the lifetime of one lock of the isopropyl gears.

As the temperature is lowered still further, first one of the benzyl rotations slows to the slow exchange limit. Finally, at still lower temperature, the other benzyl rotation slows to the slow exchange limit. Once all three of these rotations have slowed enough, the slow exchange NMR spectrum obtains.

In ground states a benzyl rotamer can have two positions. In one position the benzene ring is above the molecular ring plane. In the other position the benzene ring is below that plane. This leads to *syn/anti* isomerism, both benzene rings on one side of the ring plane or one benzene ring on one side of the plane and the other on the other side of the plane. In each of the *syn/anti* isomers the benzyl groups are in different environments and within each methylene group the protons are in a different environment. Since $2 \times 2 \times 2 = 8$, there are eight proton environments and four AB quartets.

As the temperature is raised from the overall slow exchange limit, each of these dynamic symmetry operations are involved to give finally the fast exchange spectrum, to result in C_{2v} molecular static symmetry, and to give magnetic equivalences consistent with that symmetry.

7 AN AMINE/AMINE HYDROCHLORIDE EQUILIBRIUM WITH AMINE INVERSION

This example⁸ is interesting enough that it is included even though it may be a violation of the restriction to intramolecular events as stated in the Introduction. The discussion involves the static symmetry and also molecular inversion as a dynamic symmetry operation.

Nitrogen inversion in simple acyclic amines and with hydrocarbon substituents is usually too rapid to be observed directly by NMR. On the other hand, inversion of the hydrochloride of amines is very slow and magnetic equivalence is dictated by static symmetry alone. However, with an amine/amine hydrochloride equilibrium, nonequivalent protons in the hydrochloride can become equivalent in the amine. The amine in this example is dibenzylmethanamine.

The symmetry plane between the benzyl groups in the amine hydrochloride makes the benzyl radicals equivalent as entire radicals, but there is no static symmetry element that makes the protons of the methylene group magnetically equivalent within a benzyl radical. As a consequence the methylene protons with the methylene groups give an AB quartet. Inversion is much too slow within the hydrochloride to act as a dynamic symmetry operation.

On the other hand, inversion of the amine is rapid and acts as a dynamic symmetry operation to make the methylene protons equivalent. As the pH of the hydrochloride solution is raised, enough amine exists in the equilibrium mixture that the methylene AB quartet coalesces as the methylene protons become equivalent.

Since inversion occurs only during the amine lifetime, and the amine/amine salt equilibrium is fast, the exchange of methylene proton identities is given by $k(\text{exchange}) = k(\text{inversion}) \times (\text{amine})/[(\text{salt}) + (\text{amine})]$. With a pH of 2.5, using the $\text{p}K_{\text{a}}$ value of the amine as 7.5 and obtaining $k(\text{exchange})$ from signal shape analysis, the authors were able to calculate the inversion rate of the amine as $2 \times 10^5 \text{ s}^{-1}$. In effect the salt sequestered enough of the amine to make the inversion rate measurable.

8 EXCHANGE IN AN IRON HYDRIDE

Inorganic compounds can be a very rich source for all sorts of NMR studies. The examination of the temperature-dependent proton spectra and ^{31}P spectra of $\text{H}_2\text{Fe}[\text{P}(\text{OC}_2\text{H}_5)_3]_4$ illustrates this richness.⁹ (Of the proton spectra only the hydride part is relevant to the discussion. The spectra of ethyl protons are omitted.)

The compound exists as the *cis* isomer, (5), where the Ps represent ligand triethyl phosphite molecules and the Hs the ligand hydrogen atoms. The subscripted numbers will be used in the continued discussion. Because of space limitations, the discussion is drastically curtailed. Readers may wish to consult the original paper.

At 68°C , the spectrum of the hydride hydrogens is a binomial quintet which indicates that the protons are magnetically equivalent as are the phosphorus atoms. The proton-decoupled phosphorus spectrum is just one singlet which also indicates that the phosphorus atoms are equivalent. It must be that some exchange processes are rapid enough at this temperature to be dynamic symmetry operations that lead to the patterns of magnetic equivalence.

At -50°C , the magnetic equivalence of the phosphorus atoms has disappeared. The proton-decoupled phosphorus spectrum gives an A_2B_2 pattern which is just what would be expected from C_{2v} symmetry for the *cis* isomer.

The low temperature proton spectrum for the hydride hydrogens is a deceptively simple triplet of doublets which represents an $\text{AA}'\text{XX}'\text{Y}_2$ pattern (A for protons, X and Y for phosphorus). The authors found six different coupling constants which is consistent with such a pattern.

As the temperature is lowered from 68°C , the three central peaks of the proton quintet broaden, as would be expected if the relevant exchanges were occurring. However, the wing peaks of the quintet remain sharp and unaffected by exchange. This shows that two of the phosphorus atoms remain equivalent as the temperature is lowered. The axial phosphorus atoms are magnetically equivalent and are the Y_2 part of the $\text{AA}'\text{XX}'\text{Y}_2$ spectrum. On the other hand, the equatorial phosphorus atoms are the XX' part of the spectrum and are not magnetically equivalent.

The phosphorus spectra at intermediate temperatures were compared with calculated spectra assuming various phosphorus atom exchange schemes. The only exchange scheme that

fits the experimental spectra was to have P^1 exchange with P^3 or P^4 and to have P^2 exchange with P^3 or P^4 . Or, in other words, there was axial-equatorial exchange, but no axial-axial or equatorial-equatorial exchange of phosphorus atoms. The observed exchanges are the fundamental dynamic symmetry operations, but without revealing the mechanistic detail as to how they occur.

The authors felt that the complexity of this molecule is appropriate to demonstrate this kind of permutational analysis. Less complex molecules would not exhibit interesting exchange patterns, while more complex molecules might present too much of a computational problem. It should be noted that the development of two-dimensional NMR techniques after this paper was published provides direct instrumental access to revealing which nuclei are exchanging with which nuclei.

9 CHANGE OF SHAPE: POLYHEDRAL EXCHANGE

Four-coordinate nickel compounds often exist in solution as an equilibrium of 'square planar' and 'tetrahedral' isomers. (Generally the square planar complexes are not strictly D_{4h} and the tetrahedral complexes are not strictly T_d , but this distinction in the isomers is common in the literature and is useful. The quotation marks will be dropped in the discussion below.) The square planar isomers are diamagnetic while the tetrahedral isomers are paramagnetic. The paramagnetism in the tetrahedral isomers leads to very large shifts of NMR signals from their normal positions in diamagnetic isomers (or molecules in general). These very large shifts facilitate signal assignment in the slow exchange limit where the signal sets of the two isomers can be seen as two separate sets. It may stretch the definition somewhat, but the conversion between isomers could be called a dynamic symmetry operation. There have been detailed mechanistic proposals as to how the conversion occurs but they will not be discussed here. The components of these mechanisms could be more properly labeled as dynamic symmetry operations rather than the overall conversion.

Unfortunately in most instances the slow exchange limit is evidently below attainable temperatures and the only spectra obtained are the spectra averaged between isomers. The molecule, $[\text{MeP}(\text{Ph})_2]_2\text{NiBr}_2$, and related molecules, provide fortunate exceptions.¹⁰ At -65°C , the slow exchange spectrum demonstrates the very large chemical shifts that are induced by paramagnetism. For example, the signal from the *meta* protons in the tetrahedral isomer occurs at almost $\delta - 30$ ppm, while the corresponding signal for the square planar isomer occurs at the normal position for aromatic proton signals.

As the temperature is raised the separate signals begin to coalesce. Finally at 40°C , the averaged spectrum is obtained and with it, magnetic equivalence. The authors obtained 57 kJ mol^{-1} for $\Delta G^\ddagger$.

10 INTERCHANGE OF HYDRIDE HYDROGEN WITH MOLECULAR HYDROGEN AS LIGANDS

The dynamic symmetry operation here is the exchange back and forth, on the one hand, of two hydrogen atoms

Figure 2 The hydrogen/hydride equilibrium and the hydride region of the 250 MHz spectrum of the ion $[\text{ReH}_4(\text{CO})(\text{PMe}_2\text{Ph})_3]^+$. (Reproduced with permission from Crabtree, *Acc. Chem. Res.*, 1990, **23**, 95)

as a hydrogen molecule bound as one ligand, with the two hydrogen atoms bound separately as two separate hydride ligands, on the other hand.

This change between molecule and hydride manifests itself in several features of the variable temperature NMR spectra¹¹ of the ion $[\text{ReH}_4(\text{CO})(\text{PMe}_2\text{Ph})_3]^+$. The hydride region of the spectra is shown in Figure 2.

At 298 K, the entire hydride spectrum is just one broadened quartet with coupling to the three phosphorus atoms. The fast exchange limit and magnetic equivalence are being approached. As the temperature is lowered, this signal decoalesces quickly to give an AB quartet at high frequency (low field) and to produce an unresolved hump at lower frequency. At the lowest temperature, the low-frequency hump has decoalesced into a somewhat broadened AB quartet and a smaller hump. There must be two rate processes at work.

The higher temperature coalescence depends on the slowing down of the isomer equilibrium. The value of $\Delta G^\ddagger$ for the isomerization was found to be 49 kJ mol^{-1} at 213 K. The sharp, high frequency quartet is assigned to isomer (6a). In (6a) all the hydrogen atoms are bound to the metal as hydride hydrogens and, as a consequence, there is no further change in the spectrum of that isomer as the temperature is lowered. The spectrum of isomer (6b) continues to change as the temperature is lowered, which indicates that some

dynamic operation is coming into play. The final partial decoalescence of the spectrum of (6b) reflects the slowing down of the hydride/molecule interconversion within that isomer. The value of $\Delta G^\ddagger$ was found to be 41 kJ mol^{-1} . The interconversion has then played a role twice. This is one interesting example of the role of a dynamic process as occurring more than once in the same molecule. A number of examples have been published of multiple rotations, inversions, and combinations of these and other processes.

An interesting sidelight arises from the above experiment. Generally, 7- and 8-coordinate structures are *fluxional*. Interconversions between competing polyhedra are so rapid that the slow exchange spectrum is not attainable at the lowest temperatures that are available to NMR experiments. In the case discussed above, not only is the slow exchange spectrum of one such structure achieved, but also that of the other, competing polyhedron with a different coordination number. The 7-coordinate structure involves a molecule of hydrogen occupying only one coordination site. The 8-coordinate structure involves two hydrogen atoms, each occupying a coordination site.

11 INVERSION AND ISOMERIZATION IN METAL TRIS(DIKETONATES)

The octahedral complexes in which a metal is bonded to three β -diketone ligands provide instructive examples of the role of symmetry in NMR. ('Octahedral' is at best only approximately octahedral, but the term is used widely when discussing these complexes.) There is a very large amount of literature on this subject, but discussion here is focused on the complexes of (a) symmetrical diketones, $\text{RC}(\text{O})\text{CH}_2\text{C}(\text{O})\text{R}$, and (b) unsymmetrical diketones, $\text{RC}(\text{O})\text{CH}_2\text{C}(\text{O})\text{R}'$, and where a given complex has all three diketones as either (a) or (b).

The static symmetry of the symmetrical complexes (a) is D_3 (and not O_h). The three diketone chelate rings with the metal are all magnetically equivalent as entire rings. The complex is chiral and chirality will be apparent if diastereotopic nuclei or groups of nuclei are included. In practice it has been very useful for both R groups to be isopropyl. With this choice of ligand all the isopropyl groups are magnetically equivalent as entire groups, but the methyl groups within an isopropyl group are nonequivalent. In the slow exchange limit there will be two methyl doublets and the two will become one methyl doublet at the fast exchange limit. The dynamic symmetry operation is inversion of the complex.

The simplest visualization of the actual inversion mechanism is to assume a trigonal prism as the transition state. The transition state molecule could then either fall back into its original ground state geometry or into its enantiomer. While this mechanism has the virtue of simplicity, it is not generally accepted. Instead a dissociative mechanism is preferred. One end of one of the ligands breaks its bond to the metal such that the metal then becomes five-coordinate. The transition state geometry around the metal is supposed to be either a trigonal bipyramid or a square pyramid. The ligand that became unidentate in the transition state reattaches itself either to reform the original ground state or to form its enantiomer. These complexities admittedly stretch the concept of a single dynamic symmetry operation.

Complexes of type (b) can exist as *cis* or *trans* isomers. For the *cis* isomer there is one triangular face defined by three R groups. The vertices of the triangle opposite to this triangle are occupied by R' groups. The *cis* isomer has C_3 symmetry with the C_3 axis through the centers of the triangles above. As a consequence the three chelate rings are equivalent as entire rings. With R being isopropyl, the methyl groups are diastereotopic. The fast exchange spectrum of the methyl groups in an isopropyl group would consist of one doublet. The slow exchange spectrum would consist of two methyl doublets. Qualitatively the isopropyl spectrum of the *cis* isomer of a type (b) complex would be the same as for a type (a) complex.

On the other hand, the *trans* isomer of a type (b) complex has no static symmetry. The chelate rings are magnetically nonequivalent. With R being isopropyl, there would be six methyl doublets, two from each ring, at the slow exchange limit. However, the fast exchange limit would exhibit only one methyl doublet.

The dynamic symmetry operation for both *cis* and *trans* isomers is inversion. However, *cis* and *trans* isomers do not stand alone, each by itself. A *cis/trans* interconversion can also occur at the same time and can be considered as a dynamic symmetry operation. The discrete separation into racemization and isomerization events is considered to be difficult-to-impossible to achieve experimentally. The dissociation mechanism followed by arrangement into a five-coordinate geometry and a return to six-coordinate geometry could accomplish one or the other or both at once.

This complex situation with the tris(chelates) reflects the caveat stated in the Introduction. Straightforward dynamic NMR may reveal permutation patterns but cannot of itself supply mechanistic details.

Two studies of temperature-dependent NMR spectra particularly exemplify the discussion above. In both cases the metal was aluminum. The first¹² involved $\text{Al}(\text{Isopr}(\text{CO})\text{CH}(\text{CO})\text{Isopr})_3$ as type (a). The second¹³ study was with $\text{Al}(\text{PhCH}_2(\text{CO})\text{CH}(\text{CO})\text{Isopr})_3$ as a type (b) complex. (The formula for the isopropyl group is abbreviated as Isopr and that for the benzene ring as Ph.)

At 37°C the symmetrical complex, type (a), gives a slow exchange methyl spectrum that consists of two equal intensity doublets. At 120°C the two doublets coalesce and at 145°C the fast exchange spectrum as just one doublet is reached. At the lowest temperature isopropyl groups are equivalent as entire groups, but the diastereotopic methyl groups exhibit their nonequivalence as two doublets.

At 93°C the spectrum of the unsymmetrical complex shows 13 of the expected 16 methyl signals. At 139°C these doublets coalesce into one broad doublet. Finally, at 156°C, the one doublet sharpens. The fast exchange limit and magnetic equivalence obtain. There is no clear indication at intermediate temperatures that isomerization and inversion may be occurring as separate events in two well-defined temperature regions. The two dynamic symmetry operations must be very much entangled.

12 SLOW ROTATION AND POSSIBLE RING INVERSION IN A LANTHANUM COMPOUND

As a rule, complexes, molecules, and ions with central metal atoms with coordination number greater than six rearrange so

rapidly that the slow exchange limit and spectrum are not attainable. (They are said to be fluxional or *stereochemically nonrigid*.) Analysis indicates that with higher coordination numbers there are a number of competing polyhedra with nearly the same free energy. As a consequence there are one or more low-lying excited states that are readily accessible even at very low temperatures. As a result, magnetic equivalence persists in the variable temperature spectra of such compounds. However, macrocyclic ligands can confer enough rigidity to the structure of the complex species that slow exchange spectra become accessible. An example^{14a} is available with the lanthanum(III) complex ion (7) with 1,4,7,10-tetrakis(2-carbamoyl-ethyl)-1,4,7,10-tetraazacyclododecane (8).

Ring inversion and rotation around the amide bonds are both dynamic symmetry operations for this complex ion. (The authors do not specifically label the first process as ring inversion, but this seems to be one likely explanation of what is observed. This label is used throughout the rest of the discussion below.) The lanthanum atom is eight-coordinate. It is bound to the octadentate ligand through the four ring nitrogens and the oxygen atoms of the four amide groups. The lanthanum ion lies above the approximate plane of the macrocycle ring. There is a C_4 axis through the lanthanum atom and the center of the ring. Rotation around this axis is the static symmetry operation and it renders the four chelate rings equivalent as entire rings and the four amide groups equivalent as entire groups. The C_4 axis is the only static symmetry element. There is no symmetry plane. Much of the detail of the slow exchange structure of the complex in solution is suggested by the solid state structure of the complex.

The slow exchange disposition of the ring ethylene moieties is very important in rationalizing the slow exchange spectrum. Carbon-13 NMR shows that the carbon atoms within an ethylene moiety are nonequivalent. One carbon atom is closer to the lanthanum atom than is the other. For convenience in discussion, the carbon atoms within each ring ethylene group are described below as head- and tail-ends of the group. Also, the attached hydrogen atoms can be either axial or equatorial. Therefore, there are four environments for the ring ethylene hydrogen atoms. Also the head-and-tail arrangement of the carbon atoms alternates in going around the macrocycle ring. Hence, each of the ring nitrogens is chiral. These nitrogens are bound to four different atoms: (1) the lanthanum atom; (2) a carbamoyl-ethyl carbon atom; (3) a head carbon atom; and (4) a tail carbon atom. The hydrogen atoms are diastereotopic in both the methylene groups of the carbamoyl moieties. Also at the slow exchange limit, rotation around the amide bond in each amide group is slow.

The net result of all this is that the slow exchange spectrum for the protons should consist of two ABCD patterns, one

pattern for the ring hydrogens and one for the methylene hydrogens of the carbamoyl moiety, and finally an AB pattern for the amide nitrogen protons. Five different ^{13}C signals would be expected.

The experimental spectra in the slow exchange limit (0°C) confirmed these expectations, except that the protons attached to the amide nitrogen atom have a very small or even zero coupling constant to each other. As a consequence, two separate singlets were obtained for these protons rather than the expected AB quartet. Also the spectra for the ring hydrogens and for the hydrogens of the methylene groups of the carbamoyl moiety are so complicated, and with considerable overlap, that it is not easily possible to discern clearly two ABCD patterns. However, the authors did assign parts of these signals to specific protons or groups of protons.

A complete proton spectrum in the fast exchange limit was not given. However, the two amide proton singlets collapsed into one singlet as these protons became magnetically equivalent at 92°C . Signal shape analysis showed that the activation energy for rotation around the amide bond is 69 kJ mol^{-1} .

The ring carbon atoms coalesced in the ^{13}C spectrum at 29°C and a barrier of 60 kJ mol^{-1} was obtained. The ring carbons become magnetically equivalent, the head-to-tail difference is lost, and with it the chirality of the ring nitrogens. It would be expected that the loss of the head-to-tail difference and the axial/equatorial distinction between ring protons would lead to a collapse into a singlet for those protons at the fast exchange limit. If on the other hand some dynamic operation other than ring inversion is occurring, and the axial/equatorial difference is preserved, a doublet or possibly an AB quartet would be observed. The loss of chirality should alter the low temperature ABCD pattern of the methylene protons of the carbamoyl moiety to an AA' BB' pattern since these protons would no longer be diastereotopic in the chemical shift sense.

NMR studies of the complexes with paramagnetic lanthanides would be interesting, since chemical shift differences would be enhanced and first-order NMR patterns could result with easy analysis of these patterns. The variable temperature spectra of the paramagnetic complexes of the related tetraacetate macrocycle have been reported.^{14b} With this macrocycle the situation is further complicated by the coexistence of two isomers of the complexes. However, the expanded chemical shift scales that are obtained tend to compensate for this complication.

13 RING WHIZZING

Cyclopentadiene rings can be bonded to metals in either of two modes. In one mode, the bonding (pentahapto bonding symbolized as η^5 bonding) is to the ring as a whole. In this mode the metal is bonded to the ring as a whole rather than being bonded to one specific carbon atom in the ring (monohapto bonding or η^1). For the pentahapto situation, the protons of the ring are all magnetically equivalent as are the carbon atoms. The monohapto mode gives three sets of nuclei that are not equivalent between the sets. The proton attached to the bonded carbon atom is by itself one set (H_a , shown as A in Figure 3). The two protons in the once removed positions (H_b , shown as B) are the second set and are magnetically equivalent

Figure 3 Exchange patterns in a cyclopentadiene ring

to each other. The remaining two protons (H_c , shown as C) form the third set and are equivalent to each other.

In effect, the static symmetry of the monohapto-bonded ring is a symmetry plane perpendicular to the ring, including the bonding site and passing between the carbon atoms of each of the pairs of carbon atoms. The dynamic symmetry operation is the changing of site of the bonded-to-metal carbon atom. This operation is commonly called *ring whizzing*.

From the pentahapto-bonded ring, the proton resonance should just be a sharp singlet at all temperatures. In the fast exchange limit for the protons of the monohapto-bonded ring, rapid change in the bonding site should also lead to a singlet. While in the slow exchange limit (slow change in the bonding site), the magnetically equivalent sets should give signals from each set. In practice the lone proton gives a singlet and the remaining four protons give an AA'BB' pattern.

The ring complex $(\eta^5\text{-C}_5\text{H}_5)(\eta^1\text{-C}_5\text{H}_5)\text{Fe}(\text{CO})_2$ has a ring of each kind in the molecule and demonstrates this behavior.¹⁵ The results of a variable temperature study are shown in Figure 4.

At 30°C the fast exchange limit is achieved. The whole proton spectrum consists of just two singlets. The signal at lower frequency is from the pentahapto-bonded ring and the one at higher frequency the signal averaged over all the protons of the monohapto-bonded ring.

The signals at the slow exchange limit are assigned as follows, going from high frequency to low frequency. The multiplet at highest frequency is assigned to the two H_b and the two H_c protons as the expected AA'BB' pattern. The lower half of this pattern is assigned to the H_b protons and the other half to the H_c protons. This particular part of the overall assignment of proton signals is absolutely crucial to the rationalization of the variable temperature spectra as given below. The singlet at

Figure 4 Ring whizzing and its effect on the proton spectrum of $(\eta^5\text{-C}_5\text{H}_5)(\eta^1\text{-C}_5\text{H}_5)\text{Fe}(\text{CO})_2$. (Reproduced with permission from Cotton, *Acc. Chem. Res.*, 1968, 1, 257)

about 5.6 ppm is from the pentahapto ring protons and remains unaltered throughout the temperature changes. The singlet at about 6.5 ppm is from the lone hydrogen that is attached to the bonding carbon atom.

As the temperature is raised all the signals from the bonded ring broaden, but the high frequency half of the AA'BB' set broadens more rapidly than the lower frequency half. This shows that exchange of the H_b protons is occurring more rapidly than of the H_c protons. This, in turn, provides the decisive evidence as to how the bonding site shifts around the ring as ring whizzing (or, more elegantly, metal migration around the ring) takes place. The two plausible mechanisms are (1) a 1,2-shift or (2) a 1,3-shift. The exchange (or permutation) patterns that result are shown in Figure 3.

With the 1,2-shift, both H_bs are exchanged in each migration of the iron atom, but only one H_c. For one metal migration, the H_b exchange is twice as fast and the higher-frequency wing of the AA' BB' pattern would be expected to broaden twice as fast as the lower-frequency wing when the temperature is increased. On the other hand, with a 1,3-shift, the situation is reversed and the lower-frequency wing should broaden first.

This analysis, overall, is impressive and seems to demonstrate that not only in a general way is ring whizzing the dynamic symmetry operation, but in more detail that the 1,2-shift is the dynamic symmetry operation. A ¹³C temperature study could make the analysis even more impressive.

14 BRIDGE/TERMINAL EXCHANGE AND ISOMERISM IN A BRIDGED IRON COMPOUND

The compound under discussion could exist as any one or several of the isomers shown below.

By a combination of infrared and NMR spectroscopy and elegant reasoning, the authors¹⁶ were able to eliminate all possibilities except isomers (9) and (14). Isomer (9) has C_{2v} static symmetry with one CNCH₃ group above the plane of the paper and the other below that plane. (The above-the-plane, below-the-plane detail is omitted from the structural formulas.) There is a C₂ axis through the nitrogen atoms. (The

Figure 5 Variable temperature proton spectra of the compound (η⁵-C₅H₅)₂Fe₂(CO)₂(CNCH₃)₂. [Reprinted with permission from Adams and Cotton, *J. Am. Chem. Soc.*, **95**, 6589. Copyright (1973) American Chemical Society]

dispositions of the CH₃ groups is represented in an arbitrary fashion and does not affect the symmetry.) On the other hand, isomer (12) has no static symmetry.

The slow exchange proton spectrum at 26°C (Figure 5) reflects these symmetry considerations. The static symmetry of isomer (9) renders the cyclopentadienyl groups magnetically equivalent within the pair of these groups and does the same for the methyl groups. The signals at 5.33 and 6.37 ppm and with relative intensity 5:3 are assigned to the cyclopentadienyl and methyl groups of isomer (9). The set of signals at 5.38, 5.47, 6.23, and 7.48 ppm with relative intensity within the set of 5:5:3:3 are assigned to one cyclopentadienyl group, to the other cyclopentadienyl group, to the bridging CNCH₃ group, and to the terminal CNCH₃ group, respectively, all for isomer (12).

The signals for isomer (9) remain relatively sharp as the temperature is raised at first. Meanwhile the signals from isomer (12) are noticeably broadened even at 45°C. At about 60°C and higher the isomer (9) signals also broaden. At 97°C all the cyclopentadienyl signals coalesce into one sharp singlet and fast exchange is approached. The methyl signals have coalesced, but due to large chemical shift differences have not yet emerged from the baseline.

Two dynamic processes (or symmetry operations) must be taking place. The first, at lower temperature, is the exchange of bridge and terminal cyclopentadienyl and CNCH₃ groups within isomer (12). The second process, at higher temperature, must be that the isomerization process itself becomes rapid.

15 CONCLUSIONS

Two closely related aspects of NMR, magnetic equivalence and dynamic NMR, have been foci of investigations at least

since the Phillips paper¹ on dimethylformamide. Magnetic equivalence in the slow exchange limit can often be analyzed to reveal the static symmetry of a chemical species or at least to limit the choices of static symmetry. Structural details of species in solution (or even the gas phase) are deducible from static symmetry. Structural determination in whatever phase is always an important goal in chemistry. Structural determination by NMR is now in an advanced state of development.

1. Dynamic NMR can provide two sorts of information. Signal shape analysis can yield rate data in a range of rates that are much too fast to be accessible by classical rate experiments. Signal shape analysis is also now in an advanced state of development.
2. Dynamic NMR can provide information that bears on the mechanisms for various intramolecular motions and rearrangements. Mechanisms are always dear to the hearts of chemists. Mechanism elucidation, aided by dynamic NMR, has been successful in many cases. Nevertheless, this is a *relatively* undeveloped approach to the study of mechanisms.

It seems likely that continued development will depend heavily on an expanding combination of two endeavors. The first of these is the use of two-dimensional NMR (and perhaps, other NMR instrumental techniques) to identify mutually exchanging nuclei. The second is the application of the theory of permutation groups.

1 INTRODUCTION

Molten salts represent an interesting class of liquids possessing unique ionic interactions. In this type of liquid, the usual ion–solvent forces are replaced by ion–ion interactions and possess Lewis acid–base properties. Molten salts may be classified according to either composition and/or temperature range: (1) high temperature molten salts which generally contain only inorganic salts, and (2) room temperature molten salts which contain both organic and inorganic components. There are numerous excellent books and reviews of molten salt chemistry, however only a few contain references to NMR studies of these highly ionic liquids.^{1–5}

NMR studies of high-temperature molten salts often require special equipment (high-temperature probes, etc.), as described in a recent review article.³ Room temperature molten salts need special treatment only in the preparation of the sample itself (usually in a drybox, followed by sealing with a torch immediately after removing the sample from the drybox). Both types of molten salt have been used as the subject of basic studies by NMR over a wide range of nuclei including ¹H, ²H, ⁷Li, ¹³C, ¹⁷O, ¹⁹F, ²³Na, ²⁷Al, ³⁹K, ⁸¹Br, ⁸⁷Rb, ¹²⁷I, and ²⁰⁵Tl.

2 MICRODYNAMICS

2.1 Spin State Population

The distribution of nuclear spin states is affected by the application of low intensity radiation, resulting in a net absorption of energy and a redistribution of spin states. Removal of the source of radiation results in a return (relaxation) of the excited nuclei to ground state conditions. The rate of this relaxation process in the liquid state is controlled by rapidly fluctuating magnetic fields associated with rotational and translational motion. Theoretical models typically describe relaxation processes in terms of either rotational and/or translational correlation times. The correlation time τ_c typically represents the time taken by the involved nuclei to rotate, translate or be involved in such events as phase changes (see *Brownian Motion and Correlation Times*).

2.2 Relaxation and Correlation Times

Relaxation times are designated as either spin–lattice (T_1) or spin–spin (T_2), depending upon the type of interaction and the method used to obtain them. Relaxation rates are simply the inversion of relaxation times ($R = 1/T$). Spin–lattice (longitudinal) relaxation times (T_1) are obtained by the inversion–recovery method and spin–spin (transverse) relaxation times are obtained from either linewidth ($T_2^* \approx T_2$) or spin echo (T_2) measurements (see *Relaxation: An Introduction*). The theoretical equations that define relaxation times (rates) as a function of correlation time are relatively simple in the ‘extreme narrowing region’ where $\omega\tau_c \ll 1$ ($\omega = 2\pi\nu$). At low temperatures (approaching the solid or glassy state) where $\omega\tau_c \approx 1$, the equations become increasingly complex. In this region (T_1 minimum), one can still solve the correlation equations by assuming that $\omega\tau_c = 1$.

2.3 Relaxation Mechanisms

Relaxation studies of molten salts provide an excellent source of structural information which is difficult or impossible to obtain by other physical methods. Much useful information can be obtained from knowledge of spin–lattice (longitudinal) and/or spin–spin (transverse) relaxation times (see *Relaxation Processes: Cross Correlation and Interference Terms*). The relaxation mechanisms that may be observed include dipolar, quadrupolar, spin–rotation, chemical shift anisotropy, scalar, and paramagnetic (see *Relaxation Theory for Quadrupolar Nuclei* and *Carbon-13 Relaxation Measurements: Organic Chemistry Applications*). Of these mechanisms, paramagnetic relaxation is often the most effective. Consequently, one must be careful to exclude paramagnetic impurities from the melts under observation.

2.4 Relaxation Studies

The first significant papers on molten salt relaxation studies dealt with ¹H linewidth studies of potassium stearate.^{6,7} These early investigations demonstrate the usefulness of this technique by correlating large changes in R_2 ($= 1/T_2$) with phase transitions. A recent ¹H relaxation study⁸ of the *N*-(1-butyl)pyridinium chloride–aluminum chloride system compares intramolecular rotational correlation times with melt viscosities. The data obtained in the acidic melt⁸ region (AlCl₃ in excess) where Al₂Cl₇[−] is present, indicates that the extreme narrowing condition ($\omega\tau \ll 1$) is not met in these highly viscous melts. In the basic or neutral melts, where AlCl₄[−] is the primary anionic species, the extreme narrowing condition is apparently upheld.

In the initial studies of group I cations in high temperature molten salts^{9,10} the spin–lattice relaxation times (T_1) of ²³Na and ⁷Li in molten NaNO₃ and LiNO₃/KNO₃ mixtures are reported and the relationships between quadrupolar relaxation, diffusion and ionic radii carefully analyzed (see *Relaxation Theory for Quadrupolar Nuclei*). The conclusion¹⁰ that long-range order in the melt no longer exists as it does in the solid is supported by the fact that the largest part of the electric field gradient comes from only one neighboring anion and, therefore, models of ionic interactions in the melt should

involve only nearest neighbors. It should be pointed out, however, that the author¹⁰ assumes that ^7Li relaxes by a purely quadrupolar relaxation mechanism, although it is likely that dipolar effects are also present as is often the case for ^7Li relaxation.

This type of high-temperature study is extended¹¹ to ^{23}Na and ^{87}Rb in molten NaNO_3 and RbNO_3 . The authors¹¹ calculate field gradients around the cations using results from X-ray diffraction studies to test various models and conclude that relaxation processes from translational motion are more important than those from rotational motion. In a following report, they¹² study the relaxation of ^{81}Br and ^{127}I in molten LiBr and LiI . As is often the case, the NMR relaxation correlation times¹² differ by several orders of magnitude from those obtained from viscosity measurements of the same systems.

Chloroaluminate room temperature melts have been the focus of a number of relaxation studies (^1H , ^{13}C , ^{23}Na , and ^{27}Al).^{8, 13–16} Attempts by investigators^{8, 13} using viscosity to calculate correlation times from

$$\tau_c = \eta V / kT = 4\pi a^3 \eta / 3kT \quad (1)$$

and to determine adequately molecular size from this equation have generally been unsuccessful. The correlation times determined from viscosity are typically two orders of magnitude larger than those determined from NMR.⁸ Use of equation (1) to calculate ionic radii a from NMR correlation times also provides unrealistic values. The use of the Stokes–Einstein equation

$$D = kT / 6\pi \eta a \quad (2)$$

with diffusion coefficients to obtain complex radii is more promising.¹³

Another use of relaxation measurements involves the dual spin probe (DSP) method.^{14, 15} The DSP method requires that neighboring nuclei form a chemical bond or complex, which implies that these nuclei undergo simultaneous rotation and therefore have the same correlation time (assuming that a rotational model is appropriate). In the case of ^{13}C and ^{27}Al , this leads to approximate equality between the ^{13}C dipolar correlation time τ_{eff} and the ^{27}Al quadrupolar correlation time τ_Q :

$$R_1^{\text{dipolar}}(^{13}\text{C}) = N_H (\hbar \gamma_C \gamma_H)^2 r_{\text{CH}}^{-6} \tau_{\text{eff}} \quad (3)$$

$$R_1^Q = [(3/10)\pi^2(2I + 3)/I^2(2I - 1)][1 + (z^2/3)]\chi^2 \tau_Q \quad (4)$$

$$\chi [e^2 Q q / h] = \text{QCC} \quad (5)$$

The DSP assumptions include: (1) the asymmetry factor z is zero; (2) the intramolecular dipolar relaxation model (^{13}C) is adequate; and (3) the system is within the boundary of the extreme narrowing condition ($\omega\tau < 1$). If all these conditions are met, a plot of $R_1^{\text{dipolar}}(^{13}\text{C})$ versus R_1^Q will be linear and pass through the origin.^{14, 15} An important result of this analysis is that it provides a method for determining quadrupolar coupling constants (QCCs) in the liquid state.^{14, 15}

An alternative method for determining QCC values is to lower the melt temperature until a T_1 minimum is observed. At

this point, $\omega\tau_c \approx 1$ and the correlation equation can be solved exactly.¹⁶ This same approach can be used in all melts for ^{13}C , ^1H , and other nuclei. Solution of the correlation equations is readily accomplished using a desktop computer system.

3 CHEMICAL SHIFTS

3.1 Physical Interpretation

Chemical shift studies^{17, 18} of a series of molten thallium salts are able to relate the ^{205}Tl chemical shift to the square of the overlap integral giving a measure of the degree of covalency. In these studies, ^{205}Tl chemical shifts in Tl(I) and Tl(III) salts are reported relative to TlNO_3 as a function of temperature. The observation that TlCl_3 has a large chemical shift relative to TlNO_3 and that it undergoes a very small change upon melting leads to the conclusion that the Tl(III) atoms are deshielded by the chlorine atoms within the molecule and yet are strongly shielded from neighboring molecules within the melt. The authors^{17, 18} also conclude that Coulombic forces predominate in molten halides while in covalent species (AlCl_3) intermediate forces such as ionic, covalent, dipolar, and van der Waals forces must play roles of varying importance.

3.2 Equilibrium Constants

Chemical shift values are often used to calculate equilibrium constants of molecular and ionic complexes. The basic assumption is that the observed chemical shift is the sum of the concentration-weighted chemical shifts of the free and complexed nuclei. One can usually solve these equations using either mole fraction or molar concentration terms. The resulting information is extremely useful and relatively easy to interpret compared with attempts to analyze chemical shifts of individual species which, by definition, contain a number of complex terms (see *Shielding Calculations: LORG and SOLO Approaches*).^{17, 18} The following is a typical derivation¹⁹ of the equations necessary for equilibrium analysis given the system, $A + B \rightleftharpoons C$, where (a) $B > A$, (b) one assumes that A and C have characteristic chemical shifts δ_A and δ_C , and (c) the observed chemical shift δ_{obs} is the weighted arithmetic mean of δ_A and δ_C :

$$K = C / B_0 (A_0 - C) \quad (6)$$

$$\delta_{\text{obs}} = [C / A_0] \delta_C + [(A_0 - C) / A_0] \delta_A \quad (7)$$

If we let $\Delta = \delta_{\text{obs}} - \delta_A$ and $\Delta_0 = \delta_C - \delta_A$, then

$$\Delta / B_0 = -K (\Delta - \Delta_0) \quad (8)$$

The major advantage of equation (8) is that a plot of Δ / B_0 versus Δ will give a straight line with a slope equal to $-K$ and an intercept of $K \Delta_0$. This avoids the inherent errors produced from a plot that gives the equilibrium constant as the reciprocal of the intercept (this often results in $1/K$ values close to the origin, producing a considerable error in the value of K). There still remains, however, the problem of determining δ_A .

In molten salts, it may be necessary to plot δ_A (observed) versus $1/A$ and extrapolate to the y intercept ($A = \infty$) by the use of a polynomial fit to obtain a value of $\delta_A(\text{free})$. Iterative methods can also be used to solve equations (6)–(8).

Examples of equilibrium constant determination include studies of tetrachloroaluminate melts^{20–22} in which the cationic source is either 1-ethyl-3-methylimidazolium chloride^{20,22} or *n*-butylpyridinium chloride.²¹ The first of these studies²⁰ used ^{13}C NMR chemical shifts to establish which anionic species were present as a function of melt composition. The second study²¹ identified and analyzed the equilibrium between LiCl_2^- and the LiCl_2^- dimer using ^7Li NMR. The last report²² examined the equilibrium between HCl , Cl^- , and HCl_2^-

using ^2H NMR and provides an excellent example of the use of the iterative method.

3.3 Contaminant Species

A problem that always exists in molten salt studies is the possible presence of water (and similar contaminants) resulting in the formation of various oxides. The presence of these impurities have led to several honest misinterpretations of NMR spectra in the literature. An important ^{17}O NMR study of chloroaluminate melts containing water has analyzed this problem in careful detail.²³

4 CHEMICAL EXCHANGE

4.1 Categories of Molecular Events Based on Rate of Occurrence

These categories include: (a) equilibrium species whose interconversion is slow relative to the NMR timescale, thus providing specific chemical shifts for each species; (b) species whose interconversion is extremely rapid relative to the NMR timescale, resulting in an average chemical shift which includes all equilibrium components commensurate with their relative concentration; and (c) species whose interconversion is intermediate on the NMR timescale. In the case of (c), one may observe a ‘coalescence’ of NMR signals which collapse into a single broad signal as the temperature is raised. The existence of such a ‘coalescence’ is necessary evidence that a dynamic chemical exchange process is actually occurring [species whose chemical shifts are similar undergo changes in T_2 (line broadening) as a function of temperature, producing spectra that give the false appearance of chemical exchange]. Furthermore, the analysis of such an exchange is best accomplished when the chemical shifts of the individual species are cleanly separated. Attempts to separate peaks that overlap severely can only result in significant errors (see *Chemical Exchange Effects on Spectra; Relaxation Effects of Chemical Exchange*).

4.2 Examples of Chemical Exchange

The most obvious examples of chemical exchange to be studied involve room temperature chloroaluminate melts and

^{27}Al NMR. The primary species expected to undergo exchange are included in the equilibrium

The ^{27}Al chemical shifts of the tetrachloro- and heptachloroaluminate anions given above are similar, creating a large error in any attempted mathematical analysis based on lineshapes alone. Unfortunately, studies of the chemical exchange (^{27}Al) of molten salts, where the authors have attempted to analyze equation (10), either deal with an impurity in the form of an oxide or else fail to provide examples of ‘clean’ reversible coalescence, as suggested earlier. The questionable use of preacquisition delay⁵ is also present in a number of the aforementioned analyses. A comprehensive review⁵ of ^{27}Al NMR is highly recommended, as it points out some of the many discrepancies in the few ^{27}Al chemical exchange papers in the literature.

5 DIFFUSION COEFFICIENTS

5.1 Introduction

The latest NMR method for determining self-diffusion coefficients involves the use of pulsed field gradients, as first demonstration by Stejskal and Tanner.²⁴ The recent availability of field gradient coils for all high-field NMR spectrometers guarantees that this technique²⁴ will replace various other methods (gravimetric, electrical, optical, radioactive, and stable tracers) that have been used to obtain diffusion data in molten salts (see *Diffusion Measurements by Magnetic Field Gradient Methods*).

5.2 Experimental Description

The pulsed field gradient experiment²⁴ is based on the use of two identical magnetic field pulses of duration t_1 and strength g inserted into the basic $90^\circ - \tau - 180^\circ$ spin echo sequence (see *Diffusion Measurements by Magnetic Field Gradient Methods and Field Gradients and Their Application*). The first gradient pulse is applied between the 90° and 180° rf pulses, effectively ‘labeling’ the position of individual nuclei in the sample. The second field gradient pulse is applied between the 180° pulse and the echo after a time t_2 . This second field gradient pulse monitors the movement (observation of the diffusion process) of any nuclear spins during t_2 . The effect of diffusion on the spin echo appearing at time 2τ is to decrease the echo amplitude relative to that observed in absence of gradient pulses. The echo attenuation is a quantitative measure for the precession frequency changes of diffusing nuclei during t_2 and allows the evaluation of the self-diffusion coefficient for the observed nucleus. The spin echo amplitude $M(2\tau, g)$ is given by

$$M(2\tau, g) = M(2\tau, 0) \exp\{-\gamma^2 D g^2 t_1^2 [t_2 - (t_1/3)]\} \quad (11)$$

5.3 Diffusion Coefficients

The spin echo method using pulsed field gradients was first used²⁵ successfully to determine a value of $2.30 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$

for the self-diffusion coefficient D of Na^+ in molten NaNO_3 , which is in excellent agreement with values obtained using other methods.

1 INTRODUCTION

The NMR properties of atomic nuclei in atoms, molecules, and ions depend mainly on short-range effects. For example, the chemical shift of a nucleus in a molecule depends mainly on the molecular structure and only slightly on whether the molecule is in a gas, a liquid, or a solid. In a solid, the chemical shift is anisotropic, depending on the orientation of the molecule in the magnetic field. In a liquid, the molecular motions are very rapid, so that the chemical shift is the weighted average over the solid 'powder pattern'. The liquid molecule moves very rapidly, or exchanges, among all orientations and local molecular associations. In this general sense, exchange is ubiquitous, and the results are readily understood in terms of the appropriate average. Multicomponent NMR relaxation behavior can occur when the nuclei under study are constrained in different regions or at different sites that are characterized by different time-averaged environmental parameters that affect the relaxation times. These parameters include any that affect the nuclear spin energy levels and the mobility or time dependences of these parameters.

The NMR relaxation times are expressed¹ in terms of the Fourier intensities or spectral densities $J_h(\omega)$ of the time correlation function $\langle F_h(t)F_h^*(t + \tau) \rangle$ of nuclear spin interactions $F_h(t)$ at the angular frequency ω as given by

$$J_h(\omega) = \int_{-\infty}^{\infty} \langle F_h(t)F_h^*(t + \tau) \rangle \exp(i\omega\tau) d\tau \quad (1)$$

The interaction function $F_h(t)$ is the product of a nuclear relaxation interaction strength (r^{-3} for magnetic dipolar relaxation) and a function of orientation (second-order spherical harmonic). (The average value $\langle F_h(t) \rangle$ is zero, unless there is preferential orientation such as that imposed by a stationary interface on a nonspherical molecule.) Let us consider the case when the correlation function of a site is

$$\langle F_h(t)F_h^*(t + \tau) \rangle = \langle F_h(t)F_h^*(t) \rangle \exp(-|\tau|/\tau_c) \quad (2)$$

in which the correlation time τ_c depends on the rate of molecular motion (see **Brownian Motion and Correlation Times**). Because equation (2) is an exponential function, the spectral densities $J_h(\omega)$ are given by the Lorentzian functions

$$J_h(\omega) = \langle F_h(t)F_h^*(t) \rangle \frac{2\tau_c}{1 + \omega^2\tau_c^2} \quad (3)$$

To illustrate the relationship between the spectral densities and the NMR relaxation times, consider the cases of magnetic dipolar interaction between two identical spin- $\frac{1}{2}$ nuclei and of nuclear quadrupolar interaction of a spin-1 nucleus. In both instances, the relaxation times are given by the equations¹

$$\frac{1}{T_1} = H[J_1(\omega_0) + J_2(2\omega_0)] \quad (4a)$$

$$\frac{1}{T_2} = \frac{1}{4}H[J_0(0) + 10J_1(\omega_0) + J_2(2\omega_0)] \quad (4b)$$

where T_1 is the spin-lattice relaxation time, T_2 is the transverse relaxation time, and ω_0 is the angular Larmor frequency. The interaction strength $H = \frac{9}{8}\gamma^4\hbar^2r^{-6}$ for magnetic dipolar relaxation and $\frac{9}{8}\pi^2\chi^2$ for nuclear quadrupolar interaction with zero asymmetry parameter. These equations apply (see **Relaxation Theory: Density Matrix Formulation**) to the motionally narrowed limit in which $H^{1/2}\tau_c < 1$. When this limit does not apply, the $J_0(0)$ term is incorrect and the transverse relaxation must be calculated differently. We can do this by replacing the $J_0(0)$ term with the time dependence of the ensemble average of $M_+ = M_x + iM_y$ obtained by introducing time dependence into the Larmor frequency. This is done in Sections 5–8 of this article for the transverse relaxation in many systems that involve chemical exchange of nuclei between sites with different Larmor frequencies.

In a more general approach that includes chemical exchange between different types of sites that are designated by j , we need to look closely at the evaluation of the correlation function $\langle F_h(t)F_h^*(t + \tau) \rangle$ in equation (2), which is an ensemble average (see **Relaxation Theory: Density Matrix Formulation**) to calculate NMR relaxation phenomena properly.² Take any given nucleus at time t in site j , evaluate the interaction function at this time to obtain $F_{hj}(t)$, evaluate the autocorrelation function for this nucleus at later times $t + \tau$, and continue to do this as τ increases from zero to 'large' values. Finally, take the sum over all the j -type sites, weighting each site by its fractional population P_j . Note that the fraction of time that a nucleus occupies a j -type site is equal to P_j . The average time that nucleus occupies a j -type site is τ_j .

2 RELAXATION UNDER EXTREMELY RAPID EXCHANGE CONDITIONS

If chemical exchange of nuclei is merely rapid so that all the lifetimes τ_j are long compared with the correlation times τ_{cj} , the relaxation times of nuclei in the different j types of sites are independent of the exchange, and the preceding treatment for calculating the $J_h(\omega)$ for the relaxation times of a given site j is valid. However, when the exchange is extremely rapid so that the lifetimes in a site are shorter than the correlation times, this condition is not met and the effective correlation time depends on the average lifetime in a site. There are several different cases, depending on whether the strength of the nuclear relaxation interaction is the same in the different types of sites.²

When the strength of the relaxation interaction is the same in all sites and when there is complete randomization of the interaction direction upon chemical exchange, each τ_{cj} for equation (3) is replaced by an effective correlation time

$$\tau_{\text{eff},j} = \left(\frac{1}{\tau_{cj}} + \frac{1}{\tau_j} \right)^{-1} \quad (5)$$

If the direction of interaction is retained, instead of randomized, upon exchange, the exchange process can have several different effects on relaxation.² When the rotational correlation time is much longer in one site than in another, exchange involving this site can give a very large contribution to the rate of relaxation. As a nucleus in this slow site moves by chemical exchange to a site with much faster motion, the effective correlation time for the slow site is shortened. Another possible effect is that the strength of the relaxation interaction may be changed. When the exchange is much faster than the molecular rotational motions, there is a single effective correlation time

$$\tau_{\text{eff}} = \left\{ \sum_i \frac{p_i}{\tau_{cj}} \right\}^{-1} \quad (6)$$

Also, the ensemble interaction average $\langle F_h(t)F_h^*(t) \rangle$ for a single type of site in equation (3) is replaced by the square of the weighted average of $F(t)$ at a given orientation, taken over all types j of sites, and then averaged over all orientations. This type of averaging, in the case of extremely rapid motions, is important for nonspherical molecules at the interface in many aqueous heterogeneous systems (see Section 7 of this article).

3 'TWO-SITE' CHEMICAL EXCHANGE

In all the cases described above, the nuclear relaxation is single component. However, when the nuclei are constrained in the sites, the observed NMR relaxation behavior is merely the weighted sum taken over the different sites that are characterized by specific relaxation times. When the nuclei migrate among these sites at rates that are small compared with molecular motions, the observed relaxation behavior is modified even when the relaxation time of each site is unaffected by this migration or exchange. Zimmerman and Brittin³ have treated this situation with a stochastic theory,

and McConnell⁴ has presented a mathematically equivalent approach of adding exchange terms to the Bloch equations. These modified Bloch equations are particularly convenient for discussing the simplest case that illustrates the main features of the effects of chemical exchange on NMR relaxation: exchange between two different types of sites under the condition that the relaxation time of a nucleus in a given site is independent of the lifetime of the nucleus in that given site.

The Bloch equations are written for a rectangular coordinate system that rotates at angular frequency ω about its Z axis, which is parallel to the direction of $\mathbf{B}_0$, i.e., the rotating frame of reference. The modified Bloch equations that include chemical exchange⁵ between states a and b are

$$\frac{dM_{xa}}{dt} = -(\omega_a - \omega)M_{ya} - \frac{M_{xa}}{T_{2a}} - \frac{M_{xa}}{\tau_a} + \frac{M_{xb}}{\tau_b} \quad (7a)$$

$$\frac{dM_{xb}}{dt} = -(\omega_b - \omega)M_{yb} - \frac{M_{xb}}{T_{2b}} - \frac{M_{xb}}{\tau_b} + \frac{M_{xa}}{\tau_a} \quad (7b)$$

$$\begin{aligned} \frac{dM_{ya}}{dt} &= (\omega_a - \omega)M_{xa} - \frac{M_{ya}}{T_{2a}} - \frac{M_{ya}}{\tau_a} + \frac{M_{yb}}{\tau_b} \\ &\quad - \omega_1 M_{za} \end{aligned} \quad (7c)$$

$$\begin{aligned} \frac{dM_{yb}}{dt} &= (\omega_b - \omega)M_{xb} - \frac{M_{yb}}{T_{2b}} - \frac{M_{yb}}{\tau_b} + \frac{M_{ya}}{\tau_a} \\ &\quad - \omega_1 M_{zb} \end{aligned} \quad (7d)$$

$$\frac{dM_{za}}{dt} = -\frac{M_{za} - M_{0a}}{T_{1a}} - \frac{M_{za}}{\tau_a} + \frac{M_{zb}}{\tau_b} + \omega_1 M_{ya} \quad (7e)$$

$$\frac{dM_{zb}}{dt} = -\frac{M_{zb} - M_{0b}}{T_{1b}} - \frac{M_{zb}}{\tau_b} + \frac{M_{za}}{\tau_a} + \omega_1 M_{yb} \quad (7f)$$

where ω is the angular rf frequency and $\omega_1 = \gamma B_1$, with γ the nuclear magnetogyric ratio. Also, P_a is the fraction of nuclei that are in state a , ω_a is the Larmor frequency, τ_a is the average lifetime of a given nucleus in state a before it leaves a and enters state b , T_{1a} and T_{2a} are the longitudinal and transverse relaxation times for nuclei while in state a , and M_{0a} is the equilibrium nuclear magnetization along $\mathbf{B}_0$. Similar definitions apply for state b . Since we are interested in relaxation, and relaxation times are defined in terms of the time-dependent behavior of the nuclear magnetization when $\mathbf{B}_1 = 0$, the coupled differential equations that describe the effects of chemical exchange can be written as

$$\frac{d(M_{0a} - M_{za})}{dt} = -\alpha_{1a}(M_{0a} - M_{za}) + \frac{M_{0b} - M_{zb}}{\tau_b} \quad (8a)$$

$$\frac{d(M_{0b} - M_{zb})}{dt} = -\alpha_{1b}(M_{0b} - M_{zb}) + \frac{M_{0a} - M_{za}}{\tau_a} \quad (8b)$$

for longitudinal relaxation. For transverse relaxation, it is convenient to combine the M_x and M_y magnetizations into the transverse magnetization:

$$\frac{dM_{+a}}{dt} = -\alpha_{2a}M_{+a} + \frac{M_{+b}}{\tau_b} \quad (9a)$$

$$\frac{dM_{+b}}{dt} = -\alpha_{2b}M_{+b} + \frac{M_{+a}}{\tau_a} \quad (9b)$$

In these equations, we use the definitions

$$M_{+a} = M_{xa} + iM_{ya} \quad (10a)$$

$$\alpha_{1a} = \frac{1}{T_{1a}} + \frac{1}{\tau_a} \quad (10b)$$

$$\alpha_{2a} = \frac{1}{T_{2a}} + \frac{1}{\tau_a} - i(\omega_a - \omega) \quad (10c)$$

for state a . Similar definitions apply for state b . The principle of detailed balance requires that $M_{0a}/\tau_a = M_{0b}/\tau_b$.

Equations (8a,b) and (9a,b) represent two sets of two simultaneous differential equations of the form

$$\frac{dm}{dt} = -\alpha m + bn \quad (11a)$$

$$\frac{dn}{dt} = -\beta n + am \quad (11b)$$

The solutions of each of these sets of equations are⁵

$$m(t) = A_+ e^{-\phi_+ t} + A_- e^{-\phi_- t} \quad (12a)$$

$$n(t) = B_+ e^{-\phi_+ t} + B_- e^{-\phi_- t} \quad (12b)$$

where

$$2\phi_{\pm} = (\alpha + \beta) \pm [(\alpha - \beta)^2 + 4ab]^{1/2} \quad (13)$$

and $A_{\pm}$ and $B_{\pm}$ are related by

$$B_{\pm} = -(\phi_{\pm} - \alpha)A_{\pm}/b \quad (14)$$

The net magnetizations are given by the sum $m(t) + n(t)$. The integration constants $A_{\pm}$ and $B_{\pm}$ are determined by the values of m and n at time $t = 0$, with the aid of equation (13). These initial values of m and n are determined by the rf pulse flip angles and the nuclear magnetizations that exist when the pulse is applied.

These solutions to equation (11) fail⁵ mathematically when

$$(\alpha - \beta)^2 + 4ab = 0 \quad (15)$$

As shown later, this condition represents a point at which there is a change in behavior of the solutions when the Larmor frequencies are unequal. The appropriate solutions are

$$m(t) = \{A'[1 - \frac{1}{2}(\alpha - \beta)t] + bB't\} e^{-(\alpha+\beta)t/2} \quad (16a)$$

$$n(t) = \{B'[1 + \frac{1}{2}(\alpha - \beta)t] + aA't\} e^{-(\alpha+\beta)t/2} \quad (16b)$$

The integration constants A' and B' are also determined by the initial conditions.

4 RELAXATION FOR THE CASE OF EQUAL LARMOR FREQUENCIES

4.1 General Case

Here, we apply an rf pulse and examine the subsequent behavior of the longitudinal and transverse magnetization.

We define the relaxation curve as the time dependence of the deviation of the particular nuclear magnetization from its equilibrium value. When there is no chemical exchange and $\omega_a = \omega_b$, the NMR signal is the sum of signals from the 'uncoupled' sites, and the T_1 and T_2 relaxation curves are each the sum of two exponential functions whose preexponential coefficients and decay time constants are the intrinsic state populations and relaxation times, respectively. When chemical exchange occurs, we see from equations (12a) and (12b) that the NMR signal is *still* the sum of two exponential functions. For convenience, we designate state a as that with the longer relaxation time. The mathematical form of the T_1 and T_2 curves is

$$F(t) = P'_a \exp\left(-\frac{t}{T'_a}\right) + P'_b \exp\left(-\frac{t}{T'_b}\right) \quad (17)$$

where T' and P' signify the apparent relaxation times and population fractions, respectively. These quantities are related to the intrinsic values by the equations

$$\frac{1}{T'_a} = C_1 - C_2 \quad (18a)$$

$$\frac{1}{T'_b} = C_1 + C_2 \quad (18b)$$

$$P'_b = \frac{1}{2} - \frac{1}{4} \left[(P_b - P_a) \left(\frac{1}{T_a} - \frac{1}{T_b} \right) + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right] / C_2 \quad (19a)$$

$$P'_a = 1 - P'_b \quad (19b)$$

in which

$$C_1 = \frac{1}{2} \left(\frac{1}{T_a} + \frac{1}{T_b} + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right) \quad (20a)$$

$$C_2 = \frac{1}{2} \left[\left(\frac{1}{T_b} - \frac{1}{T_a} + \frac{1}{\tau_b} - \frac{1}{\tau_a} \right)^2 + \frac{4}{\tau_a \tau_b} \right]^{1/2} \quad (20b)$$

Under all exchange conditions, the parameters in equation (17) obey the relationship

$$\frac{P'_a}{T'_a} + \frac{P'_b}{T'_b} = \frac{P_a}{T_a} + \frac{P_b}{T_b} = \frac{1}{T_m} \quad (21)$$

where T_m is defined as an effective mean relaxation time. This means that the initial slope of $F(t)$ in equation (17) is independent of the exchange rate between the two states—a consequence of the assumption that the inherent relaxation times are unaffected by chemical exchange. Other relationships that are useful in deriving simplified, approximate relationships for limiting cases are

$$P'_a + P'_b = P_a + P_b = 1 \quad (22)$$

$$P_a/\tau_a = P_b/\tau_b \quad (23)$$

4.2 Limiting Cases

Let us examine the case where $P_a \approx P_b$ and $T_a \gg T_b$ when the exchange rate is increased from small values. Initially, P'_a , P'_b , and T'_b are nearly equal to the inherent values, and

T_a' is decreased from T_a . With increasing exchange rate, T_a' continues to decrease, and can be completely different from T_a . When τ_b becomes of the same order of magnitude as T_b , T_b' decreases, P_b' becomes smaller than P_b , and T_a' continues to decrease. Finally, when τ_b is small compared with T_b , P_b' is very small, and the relaxation decay curve is approximately a single exponential with a relaxation time given by equation (21). Thus, exchange can cause the observed, or apparent, relaxation decay curve parameters to be completely different from the values inherent to the different types of sites.

There are several pertinent limiting cases⁶ that involve the relative values of the inherent relaxation times and the residence times.

When the exchange is very slow so that

$$\frac{1}{\tau_a} + \frac{1}{\tau_b} \ll \frac{1}{T_b} - \frac{1}{T_a} \quad (24)$$

the P_a' and P_b' values are very close to P_a and P_b ; however, the apparent relaxation times are decreased:

$$\frac{1}{T_a'} = \frac{1}{T_a} + \frac{1}{\tau_a} \quad (25a)$$

$$\frac{1}{T_b'} = \frac{1}{T_b} + \frac{1}{\tau_b} \quad (25b)$$

As the exchange rate increases, the values of T_a' and T_b' decrease and the value of P_a' increases. In the special case where the intrinsic relaxation times are very different and the lifetimes are intermediate,

$$T_b \ll \tau_a, \tau_b \ll T_a \quad (26)$$

the results are $P_a' = P_a$, $P_b' = P_b$, and

$$T_a' = \tau_a \quad (27a)$$

$$T_b' = T_b \quad (27b)$$

Clearly, this is a favorable case for the determination of lifetimes.

Finally, when the chemical exchange is very fast so that

$$\frac{1}{\tau_a} + \frac{1}{\tau_b} \gg \frac{1}{T_b} - \frac{1}{T_a} \quad (28)$$

the rapid exchange limit is obeyed in which a single average relaxation time is observed:

$$P_a' = 1 \quad (29)$$

$$T_a' = T_m \quad (30)$$

Another special case involves very different population fractions. When $T_b \ll T_a$ and $P_a \approx 1$ (which also means that $\tau_b \ll \tau_a$), the observable relaxation is approximately a single exponential with

$$\frac{1}{T_a'} = \frac{1}{T_a} + \frac{P_b}{P_a T_b + P_b \tau_a} \quad (31)$$

The observed relaxation time may bear no obvious relationship to that of type a sites. Even by changing the exchange rates by a large factor, such as by changing the temperature, the relaxation curve will not reveal that the system is two-site. The inherent relaxation times of the site types and the value of P_b might not be available from simple relaxation time measurements. This case applies, for example, to heterogeneous systems and biological materials that may have a small concentration of strongly relaxive sites, such as strong adsorption sites or paramagnetic centers. Note that if P_b is very small so that the b sites are widely spaced, τ_a may not be single valued, because the exchange will involve translational diffusion of the molecules of state a (see Section 8 of this article).

5 TRANSVERSE RELAXATION FOR THE CASE OF UNEQUAL LARMOR FREQUENCIES

5.1 General Case for the NMR Signal Following One Pulse

The effect of unequal Larmor frequencies is nonexistent for longitudinal relaxation, but transverse relaxation can be greatly increased. The following general solution⁵ of the set of equations given by equations (9a) and (9b) following the application of a pulse to a spin system at equilibrium is relatively simple because there is no transverse nuclear magnetism at the time of application of the pulse:

$$F_2(t) = \frac{M_+(t)}{M_0 \sin \theta_1} = P_{2+} e^{-(\phi_2+c)t} + P_{2-} e^{-(\phi_2-c)t} \quad (32)$$

where

$$P_{2+} = -(f + ig) e^{-idt} \quad (33)$$

$$P_{2-} = [f - i(1 - g)] e^{idt} \quad (34)$$

$$\phi_2 = \frac{1}{2} \left(\frac{1}{T_{2a}} + \frac{1}{T_{2b}} + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right) \quad (35)$$

$$f = -\frac{1}{4} \left\{ c(P_b - P_a)(\omega_a - \omega_b) + d \left[(P_b - P_a) \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} \right) + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right] \right\} (c^2 + d^2)^{-1} \quad (36)$$

$$g = \frac{1}{2} - \frac{1}{4} \left\{ c \left[(P_b - P_a) \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} \right) + \frac{1}{\tau_a} + \frac{1}{\tau_b} \right] - d(P_b - P_a)(\omega_a - \omega_b) \right\} (c^2 + d^2)^{-1} \quad (37)$$

$$|c| = [(X^2 + Y^2)^{1/2} + X]^{1/2} / \sqrt{8} \quad (38)$$

$$|d| = [(X^2 + Y^2)^{1/2} - X]^{1/2} / \sqrt{8} \quad (39)$$

with

$$X = \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} + \frac{1}{\tau_a} - \frac{1}{\tau_b} \right)^2 - (\omega_a - \omega_b)^2 + \frac{4}{\tau_a \tau_b} \quad (40)$$

$$Y = -2(\omega_a - \omega_b) \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} + \frac{1}{\tau_a} - \frac{1}{\tau_b} \right) \quad (41)$$

and θ_1 is the pulse flip angle. The algebraic sign of d is always positive; the sign of c is positive except for negative Y values. The value of ω is $\frac{1}{2}(\omega_a + \omega_b)$.

This function is even more complicated than the case of equal Larmor frequencies, and examination of limiting cases is necessary to show the effects of the Larmor frequency difference on transverse relaxation. When the exchange is slow so that the term $4/\tau_a\tau_b$ in equation (40) can be neglected, $d = \frac{1}{2}|\omega_a - \omega_b|$, $f \approx 0$, $g = P_b$, and $c = \pm \frac{1}{2}(1/T_{2b} - 1/T_{2a} + 1/\tau_b - 1/\tau_a)$. The upper algebraic sign applies when $\omega_a > \omega_b$, and the lower when $\omega_a < \omega_b$. Equation (32) then becomes

$$F_2(t) \approx -i \left\{ P_a \exp\left[\frac{1}{2}i(\omega_a - \omega_b)t\right] \exp\left[-\left(\frac{1}{T_{2a}} + \frac{1}{\tau_a}\right)t\right] + P_b \exp\left[-\frac{1}{2}i(\omega_a - \omega_b)t\right] \exp\left[-\left(\frac{1}{T_{2b}} + \frac{1}{\tau_b}\right)t\right] \right\} \quad (42)$$

Equation (42) is the sum of the two transverse magnetizations with separate frequencies, because d is not equal to zero. The decay rate of each signal increases (see **Chemical Exchange Effects on Spectra**) with increasing exchange rate, as in equations (25a) and (25b) for equal Larmor frequencies, but it is insensitive to the difference between the Larmor frequencies. This may be expected, since a nucleus that enters a state from the other state has a random phase because it has existed in the former state for many periods of the frequency difference $\omega_a - \omega_b$. When the exchange rate increases, the amount of dephasing per transfer becomes dependent on the Larmor frequency difference.

The terms e^{-idt} and e^{idt} in equations (33) and (34) represent two different nuclear magnetizations rotating at frequencies that differ by $2d$. At very slow exchange rates, as shown above, the frequency difference is $\omega_a - \omega_b$. With increasing exchange rates, as examination of equation (39) reveals, the value of $2d$ decreases. The peaks in the NMR spectrum approach each other (see **Chemical Exchange Effects on Spectra**). In general, the value of d never becomes zero, even at extremely high exchange rates such that $4/\tau_a\tau_b \gg (\omega_a - \omega_b)^2$. This means that, rigorously, there is *some* splitting in the NMR spectrum and that the NMR signal following a pulse *cannot* be a simple sum of two exponential decays when there is a difference in Larmor frequencies.

The above conclusion holds even in the specific case where $d = 0$. Examination of equations (38)–(41) shows that $d = 0$ when $1/T_{2a} - 1/T_{2b} + 1/\tau_a - 1/\tau_b = 0$. When the additional condition $(\omega_a - \omega_b)^2 = 4/\tau_a\tau_b$ holds, the special case in equation (15) holds, and the relatively simple solutions in equations (16a) and (16b) describe the NMR signal. This signal is

$$F_2(t) = -\frac{1}{2}(P_b - P_a)(\omega_a - \omega_b)t e^{-\phi_2 t} - i \left[1 + \frac{1}{2}(P_b - P_a) \times \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} \right) t + \frac{1}{2} \left(\frac{1}{\tau_a} + \frac{1}{\tau_b} \right) t \right] e^{-\phi_2 t} \quad (43)$$

Clearly, this is not a simple exponential decay.

When the exchange rate is very large so that the conditions $1/\tau_a, 1/\tau_b \gg 1/T_{2a}, 1/T_{2b}$, $|(\omega_a - \omega_b)|$ and

$(\omega_a - \omega_b)^2 \gg (1/T_{2a} - 1/T_{2b})^2$ prevail, $F_2(t)$ is closely approximated by

$$F_2(t) = \sin(\omega_{av}t) e^{-t/T_2} \quad (44)$$

where

$$\omega_{av} = P_a\omega_a + P_b\omega_b \quad (45)$$

$$\frac{1}{T_2} = \frac{1}{T_m} + \frac{P_a P_b \tau_a \tau_b}{\tau_a + \tau_b} (\omega_a - \omega_b)^2 \quad (46)$$

This expression shows that the difference in Larmor frequencies enhances the transverse relaxation when the chemical exchange is fast. As the exchange rate increases to extremely large values, the observed T_2 value approaches T_m , the relaxation time when the Larmor frequencies are equal.

5.2 General Case for the NMR Signal Following Two

Pulses

As usual, the NMR signal following the second pulse, applied at time $t = \tau$, is the sum⁵ of three signals. The first signal results from the M_z component of magnetization that exists at the time of application of the second pulse. It is given by

$$\frac{M_+(t)\tau}{M_0 \sin \theta_2 [1 - (1 - \cos \theta_1)]} = F(T_1, \tau) F_2(t)\tau \quad (47)$$

where $F(T_1, \tau)$ is equation (17) evaluated at time τ for T_1 , and $F_2(t > \tau)$ is equation (32) evaluated as a function of the time after the second pulse, $t > \tau$.

The other two signals result from the transverse magnetization that exists at the time of application of the second pulse. The first is the reduced continuation of the signal following the first pulse as follows:

$$\frac{M_+(t)}{\frac{1}{2}M_0 \sin \theta_1 (1 + \cos \theta_2)} = F_2(t) \quad (48)$$

where $F_2(t)$ is given by equation (32).

The other signal is the spin echo that can be found by using the complex conjugate of the one-pulse signal evaluated at time τ as the initial condition for the signal following the second (a 180°) pulse:

$$\begin{aligned} E(t) &= \frac{M_+(t)}{-\frac{1}{2}M_0 \sin \theta_1 (1 - \cos \theta_2)} \\ &= P_{E+} e^{-(\phi_2+c)t} + P_{E-} e^{-(\phi_2-c)t} \\ &\quad + [2[f \cos dt + (g+j) \sin dt] \sinh[c(t-2\tau)] \\ &\quad + 2i[f \sin dt - (g+j) \cos dt] \cosh[c(t-2\tau)]] \\ &\quad \times e^{-\phi_2 t} \end{aligned} \quad (49)$$

where

$$P_{E+} = ij e^{-id(t-2\tau)} \quad (50a)$$

$$P_{E-} = i(2g+j-1) e^{id(t-2\tau)} \quad (50b)$$

with

$$j = \frac{1}{2} - g - \frac{1}{2} \frac{c^2 + \frac{1}{4}(\omega_a - \omega_b)^2}{c^2 + d^2} \quad (51)$$

The dependences of terms in equation (49) on the quantity $t - 2\tau$ clearly show the refocusing action of the second pulse on the attenuation of the signal following the first pulse that is caused by the difference in Larmor frequencies. When the exchange rates and the Larmor frequency differences are comparable, the use of equations (16a) and (16b) shows that the spin echo signal is

$$E(t) = \frac{1}{2}(P_b - P_a)(\omega_a - \omega_b)(t - 2\tau)e^{-\phi_2 t} + i \left[1 + \frac{1}{2}(P_b - P_a) \left(\frac{1}{T_{2a}} - \frac{1}{T_{2b}} \right) t + \frac{1}{2} \left(\frac{1}{\tau_a} + \frac{1}{\tau_b} \right) t + \frac{1}{2}(\omega_a - \omega_b)^2 \tau(t - \tau) \right] e^{-\phi_2 t} \quad (52)$$

When $P_a = P_b$, comparison of equation (52) with equation (43) shows that at the time of the peak of the spin echo, $t = 2\tau$, the spin echo signal is greater than the signal from a single pulse. This refocusing phenomenon is qualitatively similar to that for the spin echoes of molecules that diffuse into different values of B_0 . Aside from a different statistical problem, the main difference here is that the precession frequency is restricted to two values; in molecular diffusion, a range of values is available to each nucleus.

Transverse relaxation is easily measured from the dependence of the spin echo amplitude at time $t = 2\tau$ determined as a function of 2τ . At very small chemical exchange rates, the Larmor frequency difference has a negligible effect on the transverse relaxation. With increasing exchange rates, the nucleus alternately experiences two different precession frequencies for random periods of time, causing a contribution to transverse relaxation by dephasing of the NMR signal. This dephasing passes through a maximum when the exchange rate and the Larmor frequency difference are comparable. Then, with increasing exchange rates, the transverse relaxation contribution from the frequency difference decreases, and is given by equation (46) when the exchange rates are large compared with the frequency difference. In the intermediate range, the spin echo time dependence is significantly modulated, and is not approximated by a sum of two exponential decays. We can readily see this from the sine and cosine terms in the time dependence of the spin echo amplitude by writing equation (49) at time $t = 2\tau$:

$$E(2\tau) = i \left[j e^{-ct} + (2g + j - 1) e^{ct} + 2f \sin dt - 2(g + j) \cos dt \right] e^{-\phi_2 t} \quad (53)$$

For zero exchange rate, $f = 0$ and $g + j = 0$; the magnitudes of these quantities increase with increasing exchange rate, become greatest when $\frac{1}{2}\pi(1/\tau_a + 1/\tau_b) \approx |\omega_a - \omega_b|$, decrease with further increase in exchange rate, and approach zero as the exchange rates approach infinity. Also, when the exchange rate is large compared with the Larmor frequency difference, the spin echo amplitude closely approximates an exponential decay with a T_2 value given by equation (46). Calculations⁵ of the decay curves show that when $T_{2a}, T_{2b} \approx \infty$, the shapes are closely approximated by exponential decays under the

condition $|\omega_a - \omega_b| \ll 1/\tau_a, 1/\tau_b$. In the intermediate range of $1/\tau_a$ and $1/\tau_b$ values, the decay curves are not exponential, and are modulated. If we define T_{2E}^* as the time required for the curve to decay from its initial value at $t = 0$ to $1/e$ of this value, T_{2E}^* passes through a minimum when $\frac{1}{2}\pi(1/\tau_a + 1/\tau_b) \approx |\omega_a - \omega_b|$.

5.3 The Spin Echo Amplitudes in Carr–Purcell Pulse Sequences

The spin echo for the special mathematical case, equation (52), when evaluated at time $t = 2\tau$ and compared with the single pulse signal, includes the extra term $(\omega_a - \omega_b)^2 \tau^2$; this suggests that the contribution of the Larmor frequency difference to the transverse relaxation can be eliminated by using the Carr–Purcell sequence with sufficiently small pulse separations. The effect of each 180° pulse in the sequence can be calculated by using the complex conjugate of the transverse magnetization at the time of the pulse as the initial condition for the solutions, equations (12a) and (12b), of equations (11a) and (11b) for the time after the pulse. We might expect that the plot of the peak spin echo amplitudes is a sum of two exponential decays or, one exponential when the exchange rates are rapid. Much theoretical work has been done for various cases to obtain exchange rates from Carr–Purcell sequences,^{7–9} and complete solutions for the two-site case are available.^{8,9} Generally, computer-assisted calculations are needed to analyze experimental data. From the complex preexponential coefficients, we may anticipate that alternations in echo amplitudes could occur along the pulse sequence, especially in cases where the exchange rates and the Larmor frequency differences are of the same order of magnitude. The early echoes observed in Carr–Purcell sequences frequently show amplitude alternations. This behavior may be related to the alternations in consecutive spin echo amplitudes for powder pattern distributions of Larmor frequencies, calculated in Section 6.2.1 of this article. These alternations die away with a time constant that is comparable to the reciprocal of the exchange rate. The shift of the peak of the first echo, and presumably other odd-numbered echoes, to ‘short’ times may also be related to this.

6 ‘MULTIPLE SITE’ CHEMICAL EXCHANGE AND TRANSVERSE RELAXATION

6.1 Gaussian Frequency Distribution

The mathematical treatment of the general multiple-site case is extremely complicated. However, the case of a continuous Gaussian distribution¹⁰ of Larmor frequencies ω_j is tractable mathematically and computationally. The results parallel those of the two-site case and are instructive. If the nucleus exchanges among the ω_j values so that the covariance function

$$\langle \Delta\omega(t) \Delta\omega(t + \tau) \rangle = \langle \Delta\omega(t)^2 \rangle e^{-\tau/\tau_c} \quad (54)$$

is obeyed then the decay curve following a single pulse is

$$F_2(t) = \exp \left[-\sigma^2 \tau_c^2 \left(e^{-t/\tau_c} + \frac{t}{\tau_c} - 1 \right) \right] \quad (55)$$

where σ is the rms value of $\Delta\omega = \omega_j - \omega_0$ and τ_e is an exchange time. The signal following the second pulse that is applied at time $t = \tau$ is

$$F_2(t)\tau = \exp \left[-\sigma^2 \tau_e^2 \left(\frac{t}{\tau_e} - 3 - e^{-t/\tau_e} + 2e^{-\tau/\tau_e} + 2e^{-(t-\tau)/\tau_e} \right) \right] \quad (56)$$

and the maximum value of this signal occurs at time

$$t_m = \tau_e [\ln(2e^{\tau/\tau_e} - 1)] \quad (57)$$

Equation (57) shows that $t_m < 2\tau$. For very slow exchange, t_m is nearly equal to 2τ . However, $t_m = 1.4899\tau$ when $\tau_e = \tau$; this is a large shift from the expected value, 2τ . The conventional spin echo amplitude curve is given by equation (56) evaluated at time $t = 2\tau$:

$$E(2\tau) = \exp \left[-\sigma^2 \tau_e^2 \left(\frac{2\tau}{\tau_e} - 3 - e^{-2\tau/\tau_e} + 4e^{-\tau/\tau_e} \right) \right] \quad (58)$$

We can examine the time dependences of these functions by defining T_2^* as the time required for equation (55) to decay from its initial value at $t = 0$ to 1/e of this value, and T_{2E}^* as the comparable quantity for equation (58). When the exchange rate is fast (i.e., $\sigma\tau_e \ll 1$), both of the above curves approximate exponential decays with decay rates

$$\frac{1}{T_2^*} \approx \frac{1}{T_{2E}^*} = \sigma^2 \tau_e \quad (59)$$

This result agrees with equation (46) for the two-site case. Also, in qualitative agreement with the two-site case, with changing exchange rate, T_{2E}^* passes through a minimum at $\sigma\tau_e \approx 1$. With decreasing exchange rate, the decay curve $E(2\tau)$ becomes

$$E(2\tau) \approx \exp \left(-\frac{2}{3} \frac{\sigma^2 \tau^3}{\tau_e} \right) \quad (60)$$

below the T_{2E}^* minimum. However, equation (60) shows that T_{2E}^* becomes equal to $(12\tau_e/\sigma^2)^{1/3}$ instead of the value τ_e that is found in the two-site case. This dependence of the attenuation of the spin echo amplitude on τ^3 is analogous to that of nuclei diffusing¹¹ in a gradient in B_0 (see *Diffusion Measurements by Magnetic Field Gradient Methods*). When a molecule diffuses, there is a Gaussian probability distribution of changes in Larmor frequency; the width of this distribution increases in time. Also, with decreasing exchange rate, T_2^* monotonically decreases and asymptotically approaches the constant value $\sigma^{-1}\sqrt{2}$.

6.2 Powder Pattern Frequency Distribution

6.2.1 'Rotational Diffusion' Site Exchange

A logical choice for ω_j values is that which appears in NMR magnetic dipolar splitting and nuclear quadrupolar splitting:

$$\omega_j = C(3 \cos^2 \theta_j - 1) \quad (61)$$

in which C is the splitting constant. For a 'powder' sample, the values of P_j are directly proportional to $\sin \theta_j$ and the number of different sites is very large. The resultant mean square value of ω_j is $\frac{4}{5}C^2$.

The rotational diffusion case¹² allows direct exchanges only between sites with adjacent θ values and thus between adjacent frequencies. The signal following one pulse can be computed¹² by solving the differential equation

$$\begin{aligned} \frac{\partial A}{\partial t} = & (6\tau_e)^{-1} \cot \theta \frac{\partial A}{\partial \theta} + (6\tau_e)^{-1} \frac{\partial^2 A}{\partial \theta^2} \\ & + iC(3 \cos^2 \theta - 1) \end{aligned} \quad (62)$$

as a function of time using the initial condition $A_j(0, \theta_j) = P_j$. The NMR signal following the second pulse is computed by using the complex conjugate $A_j^*(\tau, \theta_j)$ as the initial condition for equation (62). As in the Gaussian case, T_2^* is the time at which the signal following one pulse has 1/e times the value at time $t = 0$; T_{2E}^* is the value of 2τ at which the NMR signal following the second pulse has 1/e times the value at $2\tau = 0$. When the exchange is fast (i.e., $C\tau_e \ll 1$), both the T_2 and T_{2E} curves approximate exponential decays with decay rates

$$\frac{1}{T_2^*} \approx \frac{1}{T_{2E}^*} = \frac{4}{5}C^2\tau_e \quad (63)$$

in agreement with equation (46) for the two-site case and equation (59) for the Gaussian case. Also in agreement with these cases, with decreasing exchange rate, T_{2E}^* passes through a minimum at $(\frac{4}{5})^{1/2}C\tau_e \approx 1$. With further decreases in exchange rate, the spin echo amplitude asymptotically approaches

$$E(2\tau) \approx \exp \left(-\frac{8}{15} \frac{C^2 \tau^3}{\tau_e} \right) \quad (64)$$

so that T_{2E}^* becomes equal to $(15\tau_e/C^2)^{1/3}$. Simultaneously, T_2^* decreases monotonically and approaches the constant value $T_2^* = 1.46/C$.

The computed NMR signals in multiple pulse sequences¹² show several interesting features. When pulses are applied at times $t = 0, \tau, 3\tau, 5\tau$, etc., the amplitudes calculated at times $2\tau, 4\tau, 6\tau$, etc., increase when the number of pulses per unit time increases. The result is analogous to that for liquid molecules diffusing in a magnetic field gradient.¹¹ In addition, the odd-numbered spin echoes in a given multipulse sequence, calculated at the above times, are of smaller amplitude than the even-numbered echoes. This amplitude alternation decreases with succeeding spin echoes. The time constant for this decay appears to be equal to τ_e . An alternation of spin echo amplitudes in multiple pulse sequences is also predicted and observed¹¹ for liquid molecules flowing in a magnetic field gradient (see *Diffusion and Flow in Fluids*).

Also, as calculation of the NMR signal shapes for three pulses shows, this formalism predicts that the peak of the first spin echo, as in the Gaussian case, is shifted to times shorter than 2τ . This shift appears to be given approximately by equation (57), which was derived for the Gaussian case.

However, the peak value of the calculated second spin echo appears at the expected time, $t = 4\tau$. This predicted shift of the first echo peak but not of the second is indeed observed experimentally^{12,13} in aqueous heterogeneous systems.

6.2.2 Random Site Exchange

We can predict the NMR behavior of systems with other chemical exchange dynamics¹⁴ by generalizing equations (11a) and (11b) to allow direct exchange among many types of sites that are characterized by different frequencies. To emphasize the contribution of the Larmor frequency distribution to transverse relaxation, we set the T_2 values in equation (10c) equal to infinity.

The total transverse magnetization of a system of N types of sites is

$$M_+(t) = iM_0 \sum_{j=1}^N P_j A_j(t, \omega) \quad (65)$$

where P_j is the occupation probability of sites of type j normalized so that

$$\sum_{j=1}^N P_j = 1 \quad (66)$$

We express the time dependences of the A_j by the set of N coupled differential rate equations

$$\frac{\partial A_j}{\partial t} = i\omega_j - \frac{A_j}{\tau_j} + \sum_{\substack{k=1 \\ k \neq j}}^N \frac{A_k}{\tau_{kj}}, \quad j = 1, 2, \dots, N \quad (67)$$

where ω_j is the difference frequency (compared with the average frequency) for j -type sites, τ_j is the average lifetime of a nucleus in j -type sites, and $1/\tau_{kj}$ is the average rate at which nuclei in k -type sites move to j -type sites.

To solve the set of N equations in equation (67), we must specify the frequencies (ω_j values), occupation probabilities (P_j values), and exchange probabilities (τ_j and τ_{kj} values). We choose the powder pattern frequencies as described by equation (61) and P_j values that are directly proportional to $\sin \theta_j$. The exchange probabilities implicit in the preceding sections of this article represent one extreme case. The opposite extreme case is to allow direct exchanges between sites of all the different frequencies. This case more closely corresponds to the two-site case in that the individual exchange events can involve large changes in Larmor frequency. To set up the exchange probabilities, we use the principle of detailed balance, which requires that the total number of exchanges per second between sites j and k is directly proportional to the product $P_j P_k$. Then, if we define $1/\tau_e$ as the average rate for nuclei to leave the sites that they occupy, we obtain

$$\frac{1}{\tau_j} = V \sum_{\substack{k=1 \\ k \neq j}}^N P_k = V(1 - P_j) \quad (68)$$

$$\frac{1}{\tau_{kj}} = V P_j \quad (69)$$

where

$$V = \left[\tau_e \left(1 - \sum_{j=1}^N P_j^2 \right) \right]^{-1} \quad (70)$$

When N is very large, $V = 1/\tau_e$.

The signal following one pulse¹⁴ can be calculated by solving equation (67) as a function of time using the initial condition $A_j(0, \omega_j) = P_j$. The T_{2E} curves¹³ can be computed by using the complex conjugate $A_j^*(\tau, \omega_j)$ as the initial condition after the second pulse in evaluating the signal at time τ after the second pulse. When the exchange is fast (i.e., $C\tau_e \ll 1$), both the T_2 and T_{2E} curves approximate exponential decays with decay rates

$$\frac{1}{T_2^*} \approx \frac{1}{T_{2E}^*} = \frac{4}{5} C^2 \tau_e \quad (71)$$

in agreement with equation (46) for the two-site case and with the Gaussian and rotational diffusion cases. Also in agreement with the two-site case, with decreasing exchange rate, T_{2E}^* passes through a minimum at $(\frac{4}{5})^{1/2} C\tau_e \approx 1$ and approaches τ_e when $C\tau_e \gg 1$. This result represents a much stronger dependence of the spin echo attenuation on exchange rate than in the Gaussian and rotational diffusion cases. Simultaneously, T_2^* decreases monotonically and approaches the constant value $T_2^* = 1.46/C$.

In calculations of the NMR signals for the three-pulse case, the peak of the first spin echo is shifted to times smaller than 2τ , while the second echo peak remains at time 4τ . The shapes of the signals and the effects of changes in exchange rates differ between the present case and the preceding cases, and measurements of them allow us to determine which case better describes the sample under consideration.

7 PREFERENTIAL ORIENTATION, EXCHANGE, AND ORDER IN AQUEOUS HETEROGENEOUS SYSTEMS

In aqueous heterogeneous systems^{14,15} such as biological tissue, biopolymer gels, polyelectrolyte solutions, clay–water gels, etc., the water molecule or a hydrated ion such as sodium can be located in the bulk liquid or at the solid/liquid interface. The nonspherical bonding and electric charge distribution (electric dipole and quadrupole moments) strongly affect the motions and arrangements of water molecules at the interface. When a water molecule is at the solid surface, its motion is slowed down, and some orientations with respect to the local surface plane are more probable than others. This preferential orientation due to the nonspherical interaction causes different rotational rates about different molecular axes. The structure of the interfacial water is different from that of bulk water because this water interacts differently with the relatively immobile solid material compared to other rapidly moving water molecules. At each allowed molecular orientation at the surface, there is a different magnetic dipolar interaction of the protons (H_2O) or nuclear quadrupolar interaction of the deuterons (D_2O). The water molecules not only occupy the various site environments at the interface, but they migrate

among them and also into the bulk liquid away from the interface. This rapid chemical exchange enables all of the water molecules to experience the interfacial environment. Consequently, the spectral densities $J_h(\omega)$ that determine NMR relaxation phenomena are influenced by the effects on the correlation functions caused by the motions and local structure of the interface and the exchange between the bulk and interfacial sites.

The correlation functions of the water in such a heterogeneous system can be written¹⁴ as the sum over the different j environments:

$$\langle F_h(t)F_h^*(t+\tau) \rangle = \sum_j P_j \langle F_{hj}(t)F_{hj}^*(t+\tau) \rangle \quad (72)$$

where the sum of the occupation probabilities P_j is unity. We now assume, with good evidence, that all local permitted molecular reorientations and all local chemical exchange rates are rapid compared with the Larmor frequency ω_0 . Then, at times τ that are long compared with $1/\omega_0$, nuclei that were in a given j at time t are now distributed among all the different j sites in accordance with P_j , and $\langle F_{hj}^*(t+\infty) \rangle = \langle F_h^*(t) \rangle$. Also, for each of these nuclei, the value of $F_{hj}^*(t+\infty)$ is independent of the value of the original $F_{hj}(t)$, and equation (72) can be written as

$$\begin{aligned} \langle F_h(t)F_h^*(t+\infty) \rangle &= \langle F_h(t) \rangle \langle F_h^*(t+\infty) \rangle \\ &= \langle F_h(t) \rangle \langle F_h^*(t) \rangle \\ &= \langle F_h(t) \rangle \langle F_h^*(t) \rangle \end{aligned} \quad (73)$$

In a bulk liquid, the values of $\langle F_h(t) \rangle$ and $\langle F_h^*(t+\infty) \rangle$ at such long times are zero. However, preferential molecular orientation at the interface can result in nonzero values.

Let us temporarily assume that the surface is an infinite plane, so that the interface is planar. The orientation of the interface in $\mathbf{B}_0$ is defined by the 'director', which is normal to the surface. For simplicity, let the molecular orientation distribution be axially symmetric about the director. If the orientation of the director in $\mathbf{B}_0$ is given by the polar and azimuthal angles θ' and ϕ' , and the orientation of the nuclear spin interaction vector with respect to the director is given by the polar and azimuthal angles θ'' and ϕ'' , then $\langle F_0(t) \rangle = \langle 3 \cos^2 \theta - 1 \rangle$ is given by

$$\langle 3 \cos^2 \theta - 1 \rangle = \frac{1}{2} (3 \cos^2 \theta' - 1) \langle 3 \cos^2 \theta'' - 1 \rangle \quad (74)$$

The last term on the right-hand side of equation (74) expresses the preferential orientation. The correlation function is then given by

$$\begin{aligned} \langle F_h(t)F_h^*(t+\tau) \rangle &= \langle F_h(t)F_h^*(t) \rangle \\ &\times \left(P_p e^{-\tau/\tau_{cp}} + \sum_{j=1}^{p-1} P_j e^{-\tau/\tau_{cj}} \right) \end{aligned} \quad (75)$$

where

$$P_p + \sum_{j=1}^{p-1} P_j = 1 \quad (76a)$$

$$P_p = \frac{\frac{1}{4} (3 \cos^2 \theta' - 1)^2 \langle 3 \cos^2 \theta'' - 1 \rangle_{av}^2}{\langle F_0(t)F_0^*(t) \rangle} \quad (76b)$$

The τ_{cj} are short correlation times that result from the rapid molecular motions, including exchange. The correlation time associated with the preferential orientation, τ_{cp} , is infinite in the present case.

When τ_{cp} is extremely long, its contributions to $J_1(\omega_0)$ and $J_2(2\omega_0)$ in the relaxation times given in equations (4a) and (4b) are extremely small and can be neglected. However, the $J_0(0)$ term in equation (4b) is incorrect, and the contribution of the terms that involve τ_{cp} to transverse relaxation must be calculated differently. The term $3 \cos^2 \theta - 1$ in equation (74) is $F_0(t)$, and a nonzero average value causes a residual magnetic dipolar or nuclear quadrupolar splitting in the NMR spectrum due to the preferential orientation. From equation (61), this residual splitting is

$$\omega' = \frac{1}{2} C (3 \cos^2 \theta' - 1) \langle 3 \cos^2 \theta'' - 1 \rangle \quad (77)$$

where C is the splitting constant for a stationary molecule. At any instant of time, a certain number of water molecules are preferentially oriented by the interface, so that these molecules have a certain nonzero value of $\langle 3 \cos^2 \theta'' - 1 \rangle$ and the remainder of the molecules has a zero value for this quantity. We assume that the value of $\langle 3 \cos^2 \theta'' - 1 \rangle$ for the instantaneously preferentially oriented water molecules and the number of these molecules are independent of the number of other water molecules. When rapid exchange between these two environments occurs, all of the water experiences preferential orientation, as referred to the director, for a fraction F of the time. The value of F is the fraction of the water molecules at any instant that is preferentially oriented, and the value of ω' is

$$\omega' = C' (3 \cos^2 \theta' - 1) \quad (78)$$

where

$$C' = \frac{1}{2} F C \langle 3 \cos^2 \theta'' - 1 \rangle \quad (79)$$

The effective splitting constant C' depends on the surface-to-volume ratio of the water.

In addition to the surface-to-volume ratio, the value of C' depends on the geometry of the surface. If the surface is that of the circumference of a cylinder and if rapid exchange occurs over all of the surface of the cylinder, the value of C' is one-half of that for the same surface on a plane, and the direction of the director is along the axis of the cylinder.

A system that contains many parallel planes or cylinders with uniform distribution of water will have a doublet NMR spectrum with a splitting that varies as $3 \cos^2 \theta' - 1$. This is observed in many ordered systems such as water distributed among parallel fibers, water among parallel smectite clay platelets (smectite clay minerals are comprised of 1 nm thick aluminosilicate sheets that are many micrometers or even millimeters in length and width), and lyotropic liquid crystals.

The doublet splitting constant depends on the degree of order in the system. If the system has a large number of cylinders that are not parallel and if rapid exchange occurs among all of them, the value of C' is reduced¹⁶ by this disorder as described by the second-rank order parameter

$$S = \frac{1}{2} (3 \langle \cos^2 \theta_{C1C2} \rangle - 1) \quad (80)$$

where θ_{C1C2} is the angle between the axes of a pair of cylinders C1 and C2. When all the cylinders are parallel, $S = 1$ and the splitting constant is maximum. However, if the cylinders are randomly oriented (i.e., a powder), $S = 0$ and there is no spectral splitting. A similar statement applies to a system of sheets.

The above illustration describes the extreme case of rapid exchange and local disorder. Another case is local order and global disorder as occurs with a powder made of crystallites. A crystallite may be a domain in which there is perfect order. If the molecules are constrained in individual domains, the NMR signal is the superposition of the signals of all the domains, i.e., a powder pattern. This signal will be changed if molecules are exchanged among the domains with different orientations in B_0 . This exchange will affect the transverse relaxation, and the methods described in Section 6 of this article can be used to calculate the NMR signals for various assumed models of order/disorder. In these calculations, the ω_j values are given by equations (78) and (79). If there is less than perfect order in the domains or if the degree of order is changed, the splitting constant must be reduced by the factor in equation (80). Also, if the water content is changed, the splitting constant is changed in accordance with equation (79). The exchange lifetime τ_e will depend on the size of a domain and on the diffusion coefficient of the water. Changes in the domain size or internal order caused by purely physical treatment of the sample, without any change in chemical composition, will cause changes in the transverse NMR relaxation behavior.

These phenomena are observed in deuterium NMR measurements on aqueous biopolymer gels¹⁷ and clay-water systems.^{13,14} Values of τ_e are obtained by using the methods of Section 6 to analyze the data, and the splitting constants and the domain sizes are found. Also, when a hydrated ion such as sodium is at an interface, the distortion of the hydration atmosphere causes a nuclear quadrupolar coupling that is described by a quadrupolar coupling constant and the orientation of the director. The transverse relaxation of sodium in linear polyelectrolyte solutions is quantitatively explained¹⁶ by the scheme described above for the NMR signals of water.

8 EFFECTS OF DIFFUSIVE EXCHANGE IN HETEROGENEOUS SYSTEMS

In the preceding sections, chemical exchange has been modeled so that all nuclei in a given site environment have the same time-independent exchange or transition probability to move to different environments. However, this picture fails to describe completely the spatial aspects of the exchange process.¹⁸⁻²⁰ For example, consider the case of water in heterogeneous and biological systems. The probability per unit time that a given molecule in the interface leaves the interface may be the same for all the interfacial molecules. An interfacial molecule exchanges places with a neighboring bulk water molecule, and the interface is only a molecular layer or two in thickness. Therefore, when the bulk water is many molecular diameters in thickness, the lifetime in the bulk for a molecule that is next to the interface can be much shorter than that of a molecule that is many molecular diameters away from the interface. In order for the latter molecule to be able to exchange with the interface, it first must diffuse to the interface, taking

some time and lowering its effective exchange rate. This is not a simple diffusion problem, because the mobility of water molecules in the interface is less than that in the bulk. Also, because of proximity, a molecule that has just left the interface is likely to reenter¹⁸ the interface before a molecule away from the interface has a chance to enter the interface. The exchange rate of such molecules is thus enhanced. This can lead to some relaxation behavior that is qualitatively different from the simple exchange picture.¹⁸ Also, the occupation probability for a diffusing molecule to occupy a given volume of space is a sum of exponential decays. However, the major term of this probability is generally a single exponential. Thus, the simple exchange view provides a convenient framework that is adequate, in most cases, to formulate the effects of molecular migration on NMR relaxation and interpret experimental results.

1 INTRODUCTION

Ever since the pioneering investigations on the anisotropic reorientation of solid benzene by Andrew and Eades,¹ NMR spectroscopy has proved to be a valuable tool for the elucidation of various types of nonrigidities and fluxional behavior of molecules in both the solid and solution state: the following years have seen an ever-increasing importance of NMR methods for the detection and quantification of dynamic solid state processes. In line with the instrumental development of NMR from wideline methods to include high-resolution solid state techniques, a whole range of techniques, sensitive to a large range of correlation times τ_c , and each typical for the respective experimental approach, are available nowadays.

More traditional NMR methods for the investigation of solid state dynamics utilize spin–lattice relaxation^{2,3} in either the laboratory frame (T_1) or in the rotating frame ($T_{1\rho}$), and the calculation of second moments.⁴ These techniques have been extremely important and are still popular. Multiple pulse techniques⁵ have further made the timescale of chemical shielding anisotropy available; examples for the application of such techniques are the molecular dynamics of solid C_6F_{12} ,⁵ the reorientation of P_4 ,³ and $Fe(CO)_5$.⁶ Coherent averaging of anisotropic spin interactions by magic angle spinning (MAS) and high-power decoupling, in combination with cross-polarization (CP) techniques⁷ in order to overcome inherent sensitivity problems for low- γ and/or low natural abundance nuclei, has also opened up new possibilities for the investigation of dynamic solid state processes by means of NMR: adaptation of solution state-type NMR experiments such as lineshape analysis of exchange-broadened spectra or one- and two-dimensional (1D, 2D) magnetization transfer experiments,⁸ have become accessible for the solid state.

One prime target for the investigation of solid state dynamics has recently been the area of organic polymers^{9–12} where 2D ^{13}C exchange spectroscopy (EXSY) and 1D and 2D 2H NMR of selectively deuterated compounds are the methods of choice. The research field of organometallic chemistry has so far been fairly reluctant to use high-resolution solid state NMR techniques for the elucidation of

molecular dynamics. Where activation parameters have been determined at all, this was mostly done by considering 1H spin–lattice relaxation.¹³ Anisotropic $2\pi/n$ reorientation of aromatic ligands (n denotes the n -fold axis of the idealized geometry of the ligand) π -bonded to transition metals and CO chemical exchange in carbonyl–transition metal complexes are fairly well documented,¹³ while processes such as diene jumps¹⁴ are much less common.

Activation energies E_a of the $2\pi/n$ jump reorientation of such aromatic ligands are generally fairly uniform and quite similar in solution and in the solid state. For instance, E_a for $\eta^5-C_5H_5TM(CO)_3$ (TM = transition metal) is in the range $7–10\text{ kJ mol}^{-1}$, E_a for $\eta^6-C_6H_6TM(CO)_3$ is approximately $15–27\text{ kJ mol}^{-1}$. The $2\pi/5$ and $2\pi/6$ reorientation of the analogous permethylated ligands C_5Me_5 and C_6Me_6 (Me = methyl), respectively, in such complexes do not show significantly higher activation energies. The $2\pi/n$ jump reorientation of such ‘disk-like’ aromatic ligands is sterically not very demanding, which explains the experimental finding of fairly uniform and low activation energies for such processes. In contrast, CO exchange in transition metal–carbonyl complexes is far more sterically demanding and much more dependent on the actual crystal structure, so that activation energies for CO exchange in solid transition metal complexes are far less uniform and, in general, exceed 50 kJ mol^{-1} .¹³

In contrast to the uniform dynamic behavior found for the $2\pi/n$ reorientation of π -bonded aromatic ligands in transition metal complexes, no such uniform dynamic behavior is to be expected for the $2\pi/3$ reorientation of R_3M species, simply because a great variety of such species in an even greater variety of chemical and structural environments exists. R_3M species such as CH_3 , BH_3 , or NH_3 groups will usually show very fast $2\pi/3$ reorientation, depending on the steric constraints of their molecular environment. At very low temperatures, $2\pi/3$ reorientation of such small R_3M moieties is a tunneling process,¹⁵ and at still fairly low temperatures the onset of thermally activated $2\pi/3$ reorientation is observed.¹⁶ Rates of reorientation of such small R_3M species do correlate with the steric and electronic requirements of their molecular environment and are generally strongly temperature-dependent: the activation characteristics of thermally activated $2\pi/3$ reorientation, e.g. the internal reorientation of Me groups, normally catapult into a very fast regime at or near room temperature.

Even for much bulkier species R_3M , such as CF_3 ,^{2,5} CMe_3 ,¹⁷ $SiMe_3$,¹⁸ NMe_3 ,¹⁹ and PMe_3 ,²⁰ an enormous spread of $2\pi/3$ jump rates and activation energies is to be expected for this thermally activated process owing to the great variety of molecular and crystal structures which can accommodate this process, in addition to the rich chemistry of compounds containing Me_3M groups. For $M = C, Si, N$, and P , M will usually be in a more or less distorted tetrahedral coordination. An even greater variation of $2\pi/3$ jump rates and activation energies can be predicted for species Me_3M where M denotes a metal such as Sn or Pb : for $R_3M = Me_3Sn$, Me_3Pb , both fourfold tetrahedral or fivefold trigonal-bipyramidal coordination of $M = Sn, Pb$ are found in the solid state.

From the above it is obvious that $2\pi/3$ reorientation is a common solid state dynamic process, involving R_3M species all over the Periodic Table of the elements. Schematically we may describe this process as is shown in Scheme 1, regardless of whether $R_{A,B,C}$ are crystallographically equivalent or

Scheme 1

not. Clearly, the dynamic properties of chemically different propellers R_3M will vary greatly and, thus, will challenge the unique potential of solid state NMR to provide the appropriate window of observation for an enormous range of correlation times.

We should also address the question why one should be interested to learn about $2\pi/3$ reorientation of R_3M species in crystalline solids. For small R_3M species such as CH_3 , naturally, the quantum chemical low-temperature behavior and the gradual take-over by thermal activation are of major theoretical importance. For bulky species R_3M , with $R \neq H$, thermally activated R_3M reorientation is the focus of attention: the single crystal X-ray structures of many compounds containing R_3M fragments are known. However, X-ray crystallography cannot normally detect this random $2\pi/3$ jump process so that necessarily the static picture of such compounds obtained by diffraction methods is somewhat incomplete. The geometric, static picture from X-ray diffraction, in turn, provides important information about the potential barriers (van der Waals interactions) for the $2\pi/3$ reorientation monitored by NMR. We may, thus, expect to learn more about the subtle interplay of packing in the crystal versus the steric requirements of anisotropic R_3M reorientation. However, we cannot expect to be able to definitely separate cause and effect in this interplay.

The following practical examples are taken from a group of reorienting species Me_3M which are (i) at least, in part, fragments of molecules of known single crystal X-ray structure and (ii) accessible to high-resolution solid state NMR methods for the determination of their dynamic R_3M properties.

2 SOME ILLUSTRATIVE EXAMPLES OF R_3M REORIENTATION IN THE SOLID STATE AS VIEWED BY HIGH-RESOLUTION SOLID STATE NMR TECHNIQUES

Even if—with one exception—all the following examples have been borrowed from organotin and organolead chemistry ($R_3M = Me_3Sn$ and Me_3Pb), we do not wish to highlight a particular branch of chemistry. The examples were chosen because the entire range of very slow to very fast reorientation is represented here by one group of reasonably closely related chemicals and, in particular, because depending on the

ligands X in solid Me_3SnX or Me_3PbX , the three regimes of reorientation—fast, intermediate, slow—as discussed in Sections 2.1–2.3 are accessible at or near room temperature and, thus, can be investigated conveniently by using standard CP MAS equipment.

2.1 Fast R_3M Reorientation: Rates of the Order of 10^4 Hz

Let us consider particles CH_3 and/or Me_3M , and jump rates for the mutual exchange in these particles of the same order of magnitude as the applied B_1 field strength. Under these conditions destructive interference between coherent averaging of the 1H – ^{13}C dipolar interaction (high-power 1H decoupling) and incoherent averaging due to the (random) jump processes occurs, resulting in enhanced transverse relaxation of the observed ^{13}C magnetization and, thus, temperature-dependent ^{13}C linewidths. Rothwell and Waugh¹⁶ have theoretically and experimentally investigated this T_2 effect as a versatile tool to characterize motional processes in solids. Following Rothwell and Waugh,¹⁶ the inverse T_2 relaxation time can be written as:

$$\frac{1}{T_2} = \frac{4\gamma_I^2\gamma_S^2\hbar^2}{15r^6} I(I+1) \left(\frac{\tau_c}{1 + \omega_I^2\tau_c^2} \right) \quad (1)$$

and three regimes can be distinguished: a so-called long correlation limit ($\omega_I\tau_c \gg 1$), where the S spin linewidth (here ^{13}C) is dependent on τ_c and ω_I , an intermediate regime ($\omega_I\tau_c \approx 1$) of maximum line-broadening, and a short correlation regime ($\omega_I\tau_c \ll 1$) where the S spin linewidth is independent of ω_I but dependent on τ_c .

This type of line-broadening mechanism is illustrated in Figure 1, depicting the ^{13}C CP MAS spectra of hexamethylethane as a function of temperature.¹⁶ In the temperature

Figure 1 ^{13}C CP MAS spectra of solid hexamethylethane, Me_3C-CMe_3 , illustrating the combined effect of internal methyl group plus Me_3C reorientation in the temperature range $T = 114.4$ – 145.9 K. (Reproduced with permission of the American Institute of Physics from Rothwell and Waugh¹⁶)

Figure 2 Methyl region of 75.5 MHz ^{13}C CP MAS spectra of polymeric crystalline $(\text{Me}_3\text{Sn})_2\text{CO}_3$ in the temperature range $T = 320\text{--}383\text{ K}$ for two different decoupling field strengths ω_1 (a) 4.5×10^5 and (b) $1.96 \times 10^5\text{ rad s}^{-1}$. Note that the faster reorienting trigonal-bipyramidal Me_3Sn^1 group ($\delta^{13}\text{C} \approx -1\text{ ppm}$) is in the short correlation limit over this $T = 320\text{--}383\text{ K}$ range, while the tetrahedral Me_3Sn^2 group ($\delta^{13}\text{C} \approx 1\text{ ppm}$) is in the long correlation limit for this temperature range and, thus, shows a dependence of the ^{13}C linewidths on both T and ω_1 . The linewidth of the ^{13}C resonance of the Me_3Sn^1 group depends on the temperature but is independent of ω_1 . (Reproduced by permission of John Wiley & Sons, Ltd, from Kümmerlen and Sebald²¹)

range 114.4–145.9 K, $\text{Me}_3\text{C}^-\text{CMe}_3$ shows appropriate correlation times to allow simultaneous Me and Me_3C reorientation to be monitored by this T_2 -related method.

A useful correlation time regime for the extraction of the kinetic parameters of R_3M reorientation by this method for the reorientation of $\text{R}_3\text{M} = \text{SnMe}_3$ in solid $(\text{Me}_3\text{Sn})_2\text{CO}_3$ is reached at higher temperatures.²¹ Figure 2 illustrates the ^{13}C CP MAS spectra of $(\text{Me}_3\text{Sn})_2\text{CO}_3$ in the temperature range $T = 320\text{--}383\text{ K}$. Solid $(\text{Me}_3\text{Sn})_2\text{CO}_3$ contains two different Me_3Sn moieties (one trigonal-bipyramidal Me_3Sn^1 unit, one tetrahedral Me_3Sn^2 group) per molecular unit; in this temperature range Me_3Sn^1 is in the short correlation limit while Me_3Sn^2 is in the long correlation limit.²¹

This method, as developed by Rothwell and Waugh,¹⁶ is a truly versatile tool: it does not depend on the chemical inequivalence of exchanging sites (see below), it operates by using two easily adjustable experimental parameters (ω_1 , T), it will be relevant for a great number of solid organic and organometallic compounds at or near room temperature, and is by no means restricted to the $I\text{--}S$ combination $^1\text{H}\text{--}^{13}\text{C}$. In

our view, it should clearly contribute to the development of an attitude which no longer ‘considers the prospect of broadening due to incomplete removal of the dipolar interaction an evil’.¹⁶

2.2 Intermediate R_3M Reorientation Rates: 1D Exchange broadening Regime

Intuitively, one may be tempted to assume that in solids at ambient temperatures somewhat slower reorientational R_3M processes (depending on the nature of R and M, $\text{R}_3\text{M} \neq \text{CH}_3$) with jump rates in the range approximately $10^1\text{--}10^3\text{ Hz}$ are as common as are the faster R_3M reorientation processes discussed in Section 2.1. If we wish to obtain kinetic data in this intermediate range $10^1\text{--}10^3\text{ Hz}$, straightforward 1D variable temperature CP MAS spectroscopy, focused on the ligands R, in conjunction with lineshape analysis of the exchange broadened spectra often provides the appropriate NMR tool.

In order for this tool to be useful, the R_3M species under consideration must fulfill several conditions. The ligands R must be crystallographically inequivalent and give rise to separate isotropic resonances for the different sites involved in the exchange process at low temperatures. The accessible range of correlation times is then further defined by the external magnetic field strength B_0 (defining the separation of resonances on the chemical shift scale in Hz) plus the available CP MAS temperature range. Of course, a change of B_0 corresponds to a fictitious change in temperature and, thus, can be used to extend the range of accessible jump rates for this method. The accessible CP MAS temperature range must cover the entire range from ‘rigid on the 1D chemical shift scale’ through ‘coalescence’ to ‘fast on the 1D chemical shift scale’ to allow for lineshape simulations. If, furthermore, the condition is fulfilled that the ligands R give rise to isotropic resonances under suitable CP MAS conditions (the so-called fast spinning regime), then well-established methods^{2,3} to simulate three-site exchange broadened spectra to obtain kinetic data can be absorbed directly from existing procedures^{22–24} originally designed for solution state NMR purposes. Of course, lineshape simulation of variable temperature exchange-broadened CP MAS spectra is not a model-free procedure but depends on the components Π_{jk} of the matrix describing the exchange process:²

$$\frac{d}{dt} M_j(t) = i\omega_j M_j(t) - \frac{1}{T_{2j}} M_j(t) + \sum_k \Pi_{jk} M_k(t) \quad (2)$$

For solid state CP MAS purposes, lineshape simulations should only be used if sufficient independent evidence exists that no further causes but the R_3M three-site exchange can be responsible for lineshape changes as a function of temperature. For instance, single crystal X-ray crystallography and/or the variable temperature NMR properties of the remainder of the R_3M -containing molecule are helpful sources of information.

One type of reorienting R_3M species which often falls into the appropriate regime of reorientation rates near room temperature, allowing kinetic data to be obtained from variable temperature ^{13}C CP MAS plus lineshape analysis, are Me_3Sn groups in solid trimethyltin compounds.^{25–28} Two such examples are illustrated in Figures 3 and 4.

Figure 3 Methyl region of 75.5 MHz ^{13}C CP MAS spectra of $\text{Me}_3\text{Sn}-\text{C}\equiv\text{C}-\text{SnMe}_3$ in the temperature range $T = 236\text{--}268\text{ K}$; (a) simulation assuming three-site exchange due to Me_3Sn reorientation, (b) experimental spectra. (Reproduced with permission from Kümmerlen et al.,²⁷ copyright 1994 American Chemical Society)

The methyl region of the ^{13}C CP MAS spectra of $\text{Me}_3\text{Sn}-\text{C}\equiv\text{C}-\text{SnMe}_3$ ²⁷ in the temperature range $T = 236\text{--}268\text{ K}$ and corresponding simulations are shown in Figure 3. Solid $\text{Me}_3\text{Sn}-\text{C}\equiv\text{C}-\text{SnMe}_3$ contains two symmetry-equivalent Me_3Sn groups which at room temperature are in their respective fast exchange regime of Me_3Sn reorientation on the 1D ^{13}C CP MAS scale. At $T = 236\text{ K}$ and below, three ^{13}C resonances corresponding to three inequivalent methyl groups per Me_3Sn group are clearly resolved (see also Figure 5 on $\text{Me}_3\text{Pb}-\text{C}\equiv\text{C}-\text{PbMe}_3$ for comparison). An Arrhenius plot of Me_3Sn jump rates as a function of temperature yields an activation energy $E_a = 45.8 \pm 2.4\text{ kJ mol}^{-1}$ for Me_3Sn reorientation in solid $\text{Me}_3\text{Sn}-\text{C}\equiv\text{C}-\text{SnMe}_3$.²⁷

Figure 4 illustrates a slightly more complicated case, Me_3Sn reorientation in solid $[\text{Me}_3\text{SnN}(\text{SO}_2\text{Me})_2\cdot\text{Me}_3\text{SnOH}]$ as characterized by variable temperature ^{13}C CP MAS.^{25,26} This compound is a crystalline polymer, containing two crystallographically inequivalent trigonal-bipyramidal Me_3SnO_2 groups per molecular unit. From inspection of Figure 4 it is clear that over the entire temperature range Me_3Sn^1 and Me_3Sn^2 show different jump rates. Accordingly, different activation energies are obtained as well, $E_a = 38.6$ and 44.8 kJ mol^{-1} .

The examples shown in Figures 3 and 4 represent R_3M propellers which are truly ‘convenient’ from an experimental

Figure 4 Me_3Sn methyl region of 75.5 MHz ^{13}C CP MAS spectra of polymeric crystalline $[\text{Me}_3\text{SnN}(\text{SO}_2\text{Me})_2\cdot\text{Me}_3\text{SnOH}]$ in the temperature range $T = 243\text{--}299\text{ K}$; (a) experimental spectra, (b) simulation; scales for (a) and (b) are in Hz. This compound contains two different Me_3Sn propellers per molecular unit which display different jump rates and activation energies for this process over the entire temperature range investigated ($T = 200\text{--}299\text{ K}$). See also Figure 6 for comparison. (Reproduced with permission from Kümmerlen and Sebal, ²⁵ copyright 1993 American Chemical Society)

CP MAS point of view: moderate temperatures suffice to obtain all necessary data points. The limits of thermal stability for slower reorienting Me_3M species, or the inaccessibility of sufficiently low temperatures under CP MAS conditions in the case of faster Me_3M reorientation, can severely handicap the practical usefulness of this 1D variable temperature ^{13}C CP MAS plus lineshape analysis approach.

2.3 Slow R_3M Reorientation: 2D Exchange Spectroscopy

Under conditions where the Me_3M rate of reorientation is/becomes significantly smaller than the chemical shift differences between the ^{13}C resonances of the inequivalent methyl groups, the lineshape of these ^{13}C methyl resonances

is unaffected by the reorientational process and kinetic information can no longer be obtained from 1D ^{13}C CP MAS. At this point 2D ^{13}C exchange spectroscopy (2D EXSY) steps in, as (long) mixing times τ_m in the pulse sequence $\text{CP}-t_1-\pi/2-\tau_m-\pi/2-t_2$ ²² can accommodate the situation of slow Me_3M reorientation fairly well; in principle, useful possible durations of τ_m are only limited by the eventual onset of T_1 relaxation. This 2D EXSY solid state experiment is analogous to solution state 2D EXSY—only the ^{13}C preparation pulse is replaced by the cross-polarisation sequence for solid state applications. Not only does 2D EXSY extend the range of accessible jump rates towards slow reorientation, but also in those cases where 1D ^{13}C CP MAS is informative because the exchange-broadened ^{13}C regime is accessible, additional 2D EXSY experiments usually help to obtain better, more extensive data sets to determine activation energies from jump rates.

In contrast to the analysis of exchange broadened 1D ^{13}C CP MAS spectra, where kinetic information can only be extracted from simulations based on an explicit kinetic model of the dynamic process, 2D EXSY spectra let us directly unravel the kinetic network, model-free, by simple integration of relative off-diagonal intensities as a function of temperature and τ_m . For rather simple systems such as reorienting Me_3M species, where either the number of simultaneously present different jump rates is small or the spread of jump rates is limited, mixing times τ_m can usually be chosen to be short enough so that quantification of the dynamic process can be carried out within the limits of the initial rate approximation.²² ^{13}C 2D EXSY is particularly convenient for cases such as Me_3M reorientation owing to the fact that methyl ^{13}C resonances will usually be in the fast spinning regime, not giving rise to spinning sidebands even with fairly moderate spinning frequencies ν_{rot} .

Finally, we will consider two examples of Me_3M reorientation as seen by ^{13}C 2D EXSY. Our first example is Me_3Pb reorientation in $\text{Me}_3\text{Pb}-\text{C}\equiv\text{C}-\text{PbMe}_3$.²⁷ The room temperature ^{13}C 2D EXSY experiment depicted in Figure 5 shows that

Figure 5 Methyl region of 75.5 MHz ^{13}C CP MAS EXSY of $\text{Me}_3\text{Pb}-\text{C}\equiv\text{C}-\text{PbMe}_3$ at $T = 298\text{ K}$, mixing time $\tau_m = 600\text{ ms}$, $\nu_{\text{rot}} = 3.5\text{ kHz}$; corresponding to an Me_3Pb reorientation rate $\kappa = 0.3\text{ Hz}$. (Reproduced with permission from Kümmerlen et al.,²⁷ copyright 1994 American Chemical Society)

Figure 6 Me_3Sn methyl region of 75.5 MHz ^{13}C CP MAS EXSY of $[\text{Me}_3\text{SnN}(\text{SO}_2\text{Me})_2 \cdot \text{Me}_3\text{SnOH}]$ at $T = 220\text{ K}$, mixing time $\tau_m = 500\text{ ms}$, $\nu_{\text{rot}} = 2.2\text{ kHz}$. Note the differing off-diagonal intensities for the two different Me_3Sn propellers in this compound, due to differing rates of reorientation for Me_3Sn^1 and Me_3Sn^2 . See also Figure 4 for comparison. (Reproduced with permission from Kümmerlen and Sebal, copyright 1993 American Chemical Society)

$\text{Me}_3\text{Pb}-\text{C}\equiv\text{C}-\text{PbMe}_3$ is in a slow exchange regime on the 1D ^{13}C chemical shift scale at $T = 298\text{ K}$ —in contrast to the analogous tin compound, $\text{Me}_3\text{Sn}-\text{C}\equiv\text{C}-\text{SnMe}_3$ (see Figure 3). In addition, ^{13}C 2D EXSY proves that the three methyl groups in this Me_3Pb unit are indeed inequivalent: exchange peaks between all diagonal resonances occur. Also the ^{13}C 2D EXSY experiment on $[\text{Me}_3\text{SnN}(\text{SO}_2\text{Me})_2 \cdot \text{Me}_3\text{SnOH}]$ ²⁵ in Figure 6 serves for assignment purposes: first of all, it is easily seen from the different off-diagonal intensities that Me_3Sn^1 and Me_3Sn^2 in this compound do show different rates of Me_3Sn reorientation as was also obvious from variable temperature 1D ^{13}C CP MAS (see Figure 4 for comparison). Second, 2D EXSY in this case also proves which methyl ^{13}C resonances belong together in Me_3Sn^1 and Me_3Sn^2 , respectively.

3 SOME CONCLUDING REMARKS

We hope to have demonstrated that—beyond the specific dynamic properties of Me_3Sn or Me_3Pb groups in the solid state—high-resolution solid state NMR investigations concerned with the dynamic properties of solid organic and organometallic compounds have an important role to play for a deeper understanding of the principles governing the overall structure of a crystalline solid. The task of bulky reorienting $R_3\text{M}$ groups is to act as a sensitive probe of their intra- and intermolecular environment and its influence on the dynamic properties of $R_3\text{M}$. From a practical point of view,

better quantitative knowledge of the solid state dynamics of organic and organometallic compounds should help to prevent frustration with routine ¹³C CP MAS applications in this field of chemistry.

1 INTRODUCTION

Most recently, the term ‘*soft materials*’ is frequently used in the field of materials science. *Soft* polymers considered here are classified into soft materials, and contain polymer gels, polymer liquid crystals, vulcanized elastomers, etc., in which molecular motion is much higher compared with solid polymers. Most recently *soft* polymers have attracted attention as useful materials as detailed below.

Polymer gels consist of two components of network polymer chains and solvent. Further, a third component such as a low molecular-weight compound or polymer is often contained in the gels. Polymer gels have attracted considerable attention from the point-of-view of various physical and chemical properties.¹ For example, hydroelectrolyte gels show a dramatic change in volume in response to change in solvent composition, pH, ionic strength and temperature. They contract upon application of an electric field. Further, water-swollen polymer gels can convert chemical energy into mechanical energy. These properties lead to the vitality of polymer research and development of a diversity of interests in polymer gel systems. In order to develop new polymer materials, polymer gel design has been performed on the basis of advanced polymer science and technology. The properties of polymer gels are closely related to their structures and dynamics. From such situations, the establishment of methods for elucidating the structures and dynamics is important for making reliable polymer gel design and developing new advanced polymer gels. In polymer gels, although the mobility of network polymer chains is much higher than solids, it is much lower than solvent and the low-molecular weight molecules. Thus, by taking into account such a difference in molecular motion between the mobile and immobile regions, solid-state

high-resolution NMR proves to be a useful tool to characterize such systems.

On the other hand, liquid crystalline polymers have both positional and orientational orders in the liquid crystalline phase.² The amount of order in a liquid crystal is quite small compared with a crystal. The polymer chain is rapidly rotating around the long axis and diffusing along and perpendicular to the long axis. Such anisotropic structures induce various characteristic properties to be used as materials.

From such a background, the structure and dynamics of polymer gels, liquid crystalline polymers and vulcanized elastomers by solid-state NMR, and the diffusion process of polymer gels by pulse-field-gradient spin-echo (PFGSE) NMR have been widely used in order to make reliable polymer gel and liquid crystalline polymer designs and to develop new advanced polymer gels and liquid crystalline polymers.^{3–5} Details of this work will be described.

2 MICROSCOPIC STRUCTURE AND DYNAMICS OF POLYMER GELS

Polymer gels consist of mobile and immobile regions. For this, conventional solution NMR gives useful information about mobile regions, but sometimes not on the more rigid regions. To obtain structural information on relatively rigid regions, solid-state NMR is required. Then, in order to elucidate structure and dynamics of the immobile and mobile regions in polymer gels, we must use some appropriate NMR methods or must design special methods. In this section, some studies of microscopic structure of polymer gels by ¹H pulse NMR (including use of gradient-field) and high-resolution solid-state ¹³C NMR will be introduced.

2.1 Approach by ¹H Pulse NMR Method

In the pulse NMR experiment, high power radio-frequency (rf) pulses are applied and the free induction decay (FID) of the T_2 component is detected as a time-dependent function that becomes a measure of the mobility.^{5,3} The Fourier transform converts the FID into the corresponding frequency spectrum, in which the chemical shift gives information about chemical structures. On the other hand, the FID contains information about molecular dynamics, and so the experiment with some rf pulses gives T_1 , T_2 and the diffusion coefficient (D).⁶ T_1 and T_2 are closely related with the correlation-time for molecular motion by BPP (Bloembergen–Purcell–Pound) theory when they are governed by dipolar interactions, and D as obtained by pulse NMR under a field gradient provides information about the translational motion.⁷ Therefore, pulse NMR is useful method for the elucidation of molecular dynamics in polymer systems.

2.1.1 Volume Transition of a Poly(*N*-Isopropylacrylamide) Gel

It is known that the volume of a poly(*N*-isopropylacrylamide) (PNIPAM) gel with water as solvent experiences a transition with temperature at about 33 °C.⁸ In order to elucidate molecular motion of water in the gel through the transition temperature (T_{vt}) by temperature variation, the ¹H T_2 has been measured as a function of temperature.⁹

Figure 1 Plots of the ^1H T_2 values of H_2O in neat water (●) and in the PNIPAM gel (○) against temperature at atmospheric pressure

Figure 1 shows plots of the ^1H T_2 values of H_2O in neat water (●) and water in the PNIPAM gel (○), as a function of temperature at atmospheric pressure. The T_2 value of neat water increases as the temperature is linearly increased. This shows that the mobility of water is monotonically increased with increase in temperature in the measurement temperature range. The T_2 of H_2O in the PNIPAM gel increases as the temperature increases up to 33°C . At T_{vt} (33°C), the T_2 value is transitionally decreased. As the temperature is further increased, the T_2 value is transitionally decreased. Such behavior is similar to that of water in aqueous PNIPAM solution as reported previously.¹⁰ During the NMR measurements, the gel shrinks with an increase in temperature and exuded water is physically removed. The degree of swelling Q , which is defined by the ratio of the mass of swollen gel to the mass of dried gel and shows a measure of the size of the network. This implies that the mobility of water in the gel increases with an increase in temperature up to 33°C in spite of much smaller change of the Q value, but decreases transitionally at 33°C due to a large decrease in the Q value and increases again with a further increase in temperature during which the Q value does not change. Such a behavior can be understood by assuming that intermolecular interaction between the network polymer chains above the transition temperature occurs and so the mobility of water molecules is more restricted by the polymer networks than that below the transition temperature.

2.1.2 Gelation of Poly(*N*-isopropylacrylamide) Aqueous Solution

PNIPAM in water undergoes a phase transition from sol to gel at around 32°C .¹¹ ^1H pulse NMR experiments provide useful information about molecular motion of the polymer and solvent in the solution and gel state. The abrupt change in molecular motion for solvent in the gel is caused by the formation of the gel structure at the phase transition temperature and therefore, the change of relaxation times sensitively reflects the change of states.

The ^1H T_2 values for water in 1, 2.5, 5 and 10% w/v PNIPAM/water solutions and for neat water against temperature were measured as a function of temperature.¹⁰ The ^1H T_2 value increases as the temperature is increased up to 30°C , where an increase in T_2 means an increase in molecular motion according to BPP theory.⁷ The ^1H T_2 value of neat water increases linearly with temperature up to 50°C . At the gelation temperature (about 32°C), the ^1H T_2 value in all of the polymer solutions transitionally decreases. As temperature is further increased, the T_2 value increases again. The mobility of water increases with increasing temperature up to 30°C , then decreases transitionally at about 32°C due to the gelation of the system and increases again with a further increase of temperature. This trend is very different from that of neat water. Furthermore, it is seen that the increase in the polymer concentration leads to a decrease in ^1H T_2 for water. The molecular motion of water is restricted by an increase in intermolecular interactions between the polymer chains and water. As the polymer concentration increases up to 5% at the gelation temperature, the magnitude of the decrease for ^1H T_2 value is larger. As the concentration increases further up to 10% w/v, the magnitude of the change in T_2 value for the transition becomes smaller.

The ^1H T_1 value of water molecules in 5% w/v PNIPAM/water solution was measured as a function of temperature. The ^1H T_1 value slowly increases as does the ^1H T_2 mentioned above as the temperature is increased. At the gelation temperature, the T_1 value transitionally decreases. As the temperature is further increased, the ^1H T_1 value slowly increases. This behavior is very similar to that for T_2 . As seen from the observed ^1H T_1 and T_2 behaviors, the water molecules are in the fast motion region ($\omega\tau_c \ll 1$, where ω is the resonance frequency). At 1, 2.5 and 10% w/v solutions, similar results were obtained. Therefore, the ^1H T_1 and T_2 values for water in the PNIPAM/water system are very sensitive to the phase transition and provide dynamic information.

In PNIPAM/deuterated water solution, the ^1H T_2 signal is composed mainly of two components, a long T_2 component corresponding to the side chains and extremely short T_2 component corresponding to the main chain. The T_2 value for the main chain and side chains of PNIPAM in 10% w/v PNIPAM/deuterated water solution were determined as a function of temperature. For the main chain, at temperatures from 10 to 30°C , the T_2 value is almost constant, but at the gelation temperature (32°C) it decreases transitionally, and at temperatures of 40 – 50°C it returns to being constant. This indicates that at the gelation temperature, the molecular motion of the main chain is greatly restricted. On the other hand, for the side chains, at temperatures from 10 to 30°C the T_2 value remains almost constant, increases transitionally at the gelation temperature, and at temperatures from 40 to 50°C it becomes a constant again. This is evidence that the molecular motion of the side chains increases transitionally at the gelation temperature.

By evaporating water slowly from PNIPAM aqueous solution, a PNIPAM gel is obtained. The ^1H T_2 behavior of water for this gel is very similar to that for PNIPAM aqueous solution. This shows that temperature changes of structure and dynamics for both of these systems up to 32°C are very similar to each other.¹⁰ Further insight into structural and dynamic changes by changing temperature has been studied by high-resolution solid-state ^{13}C NMR technique.

2.1.3 Structure and Dynamics of Poly(vinyl alcohol) Gel

Amorphous-poly(vinyl alcohol) (PVA) gel prepared by repeating freeze-thaw cycles from its aqueous solution is one of the physical gels.¹² A ^1H spin echo signal of PVA gel measured is composed of three components such as a long T_2 component corresponding to the mobile region (C), a short T_2 component corresponding to the immobile region (A) and an intermediate T_2 component corresponding to the interfacial region (B), which exists between the mobile and immobile regions.¹³ It can be said that the mobile region (C) comes from the non-crosslinked region, the immobile region (A) comes from the crosslinked region and the interfacial region (B) comes from the vicinity of the crosslinked region in the gel. With an increase in the polymer concentration, ^1H T_2 of three regions are slowly decreased. This means that the molecular motion is restrained, as the polymer concentration is increased. The fractions of the corresponding three regions were determined as a function of polymer concentration. The fractions of the mobile and immobile regions are largely decreased and increased with an increase in the polymer concentration, respectively. The fraction of the intermediate region over a wide range of polymer concentrations is very small.

2.1.4 Gelation of Poly(vinyl alcohol)/Water System Under High Pressure

As mentioned above, PVA aqueous solution forms a gel by undergoing freeze-thaw cycles. The gelation is induced by network formation, and at the initial step of the gelation phase separation occurs by forming polymer-aggregation region and polymer-unaggregation regions. It has been suggested that the cause of the gel formation in PVA aqueous solution is due to the formation of intermolecular hydrogen bonds.^{14,15}

The use of variable pressure is very effective in overcoming the limited interpretability of the results obtained at atmospheric pressure. Additionally, a change in pressure is expected to provide another dimension in the investigation of aqueous PVA solution and gel because volume changes by the application of pressure lead to reduction of intermolecular distance and to a major effect on molecular motion in the system compared with experiments conducted at atmospheric pressure. As viewed from high pressure NMR experiments, it can provide more useful information about intramolecular dynamics, structures of liquids, molecular conformations and intermolecular interactions through the observation of some NMR parameters such as chemical shift, T_1 , T_2 and dipolar splitting.^{13,16} From such a situation, it can be expected that more detailed information about the dynamical behavior of PVA/water system is obtained by the application of pressure. Therefore, the dynamical behavior of PVA aqueous solution and gel through the observation of ^1H T_2 values is elucidated as a function of pressure from 1 to 500 kg cm⁻² by using high pressure ^1H pulse NMR.¹⁷

The degree of polymerization of amorphous PVA used in this experiment was 300. PVA was dissolved in D₂O at 90 °C to observe the ^1H signal from the polymer. To remove the ^1H signal from HDO, which came from chemical exchange between hydroxyl proton and deuteron in PVA and D₂O, the following procedure was performed. By adding PVA/D₂O solution into excess acetonitrile, PVA substituted hydroxyl proton by deuterium (*d*-PVA) was precipitated.

The precipitated *d*-PVA was dried by a vacuum pump. The obtained *d*-PVA was dissolved in D₂O again. This procedure was repeated three times. Deuterated PVA samples were dissolved in D₂O at 90 °C. The concentration was 10% (w/w). The solution was cooled to 25 °C and kept for 10 days (sample I). PVA chains in aqueous solution aggregate slightly by such a cooling process. For this, the ^1H T_2 value for the PVA solution was measured as a function of the elapsed time during the cooling process. It is obvious that the change of the ^1H T_2 with the elapsed time is much smaller compared with that under pressure. PVA gel was prepared from PVA/D₂O solution by repeating freeze-thaw cycles 3 times (frozen and kept at -15 °C for 3 hours, and melted and kept at 25 °C for 2 hours) (sample II).

Pulse ^1H NMR measurements were carried out at 20 MHz. ^1H T_2 was determined by the CPMG (Carr–Purcell–Meiboom–Gill) method to obtain information about the molecular motion of PVA chain in the solution state, and was determined by the solid echo pulse sequence to obtain information about the molecular motion of the immobile component in the gel state. The T_2 decay for the PVA solution was analyzed as a sum of Lorentzian-type decays and for the PVA gel was analyzed as sum of Gaussian-type decays using the nonlinear least-squares method.

In high pressure experiments, the sample cell was made from a Pyrex glass capillary tube with an outside diameter of 5.0 mm and an inside diameter of 2.6 mm. The cracks on the surface of the outside and inside of the capillary tube were etched by aqueous HF solution. The capillary was glued to a nonmagnetic stainless steel tube using epoxy resin. The pressure can be changed from 1 to 500 kg cm⁻² with no failure of the system.

From the ^1H CPMG experiments on PVA aqueous solution at room temperature, the T_2 signal is mainly composed of two components. The PVA chains in aqueous solution aggregate partly by the cooling process when the solution is prepared. From such a situation, the long T_2 component comes from the mobile region, which is assigned to non-aggregated PVA chains. The short T_2 component comes from the immobile region, which is assigned to aggregated PVA chains in the solution state. The ^1H FID signals of PVA/D₂O solution are shown as a function of pressure in Figure 2. The ^1H FID signals of PVA chains at pressures from 1 to 100 kg cm⁻² slowly decay, and at pressures over 200 kg cm⁻² the variation of decay increases. The ^1H T_2 values for PVA/D₂O solution were determined as a function of temperature. The ^1H T_2 value for the immobile region is almost a constant to be about 25 ms at pressures from 1 to 500 kg cm⁻². On the other hand, the ^1H T_2 value for the mobile region is changed by pressure. The ^1H T_2 value is lowered from ca. 650 to 600 ms in the pressure range from 1 to 100 kg cm⁻², and again decreases from ca. 600 to ca. 100 ms in the pressure range from 100 to 200 kg cm⁻². At pressures over 200 kg cm⁻², the ^1H T_2 values for the long T_2 component are constant at about 100 ms. These experimental results indicate that the molecular motion of PVA chains in the aggregated region is not changed by varying pressure up to 500 kg cm⁻², but the molecular motion in the non-aggregated region is affected by pressure in the pressure range over 200 kg cm⁻². The ^1H T_2 value for mobile component is about 320 ms and the ^1H T_2 value for mobile component at 1 kg cm⁻² decreases by applying pressure. The long T_2 component disappears in the pressure range over 200 kg cm⁻².

Figure 2 Pressure dependence of ^1H T_2 signal of PVA/D₂O solution obtained by the CPMG method

and the fraction of the short T_2 component increases up to 200 kg cm^{-2} . In the pressure range over 200 kg cm^{-2} , the short T_2 component occupies the whole fraction. From these results, it can be said that the molecular motion of PVA chains in non-aggregated region is restricted by applying pressure up to 500 kg cm^{-2} , and the process of gelation is induced. Finally, it can be said that high-pressure ^1H pulse NMR gives useful information about the dynamics of PVA chains in aqueous solution state and in gel state.

2.1.5 Structure and Dynamics of (Ethylene-Vinyl Alcohol) Copolymer Gels

Ethylene-vinyl alcohol (EVOH) copolymer gel can be prepared by repeating freeze-thaw cycles from its aqueous solution similarly to the preparation of the PVA gel. The ^1H T_2 signal of EVOH gel with a relatively high ethylene content of 32% as obtained by ^1H solid echo method was observed.¹⁸ The ^1H T_2 value is determined from the slope of the plot of $\ln M$ against t^2 , where M is the amplitude of the spin echo signal and the T_2 signal is assumed to be a Gaussian decay in the spectral analysis. According to the BPP theory for NMR relaxation, T_2 decreases continuously as the correlation time τ_c in molecular motion is increased.⁷ This means that shorter T_2 corresponds to slower molecular motion. Thus, T_2 can give dynamic information about the gels through the BPP theory. The ^1H T_2 curve is composed of three kinds of the components; the short T_2 component

corresponding to the immobile region (A), the intermediate T_2 component corresponding to the interfacial region (B), which exists between the mobile and immobile regions, and the long T_2 component corresponding to the mobile region (C). By aid of the computer-fitting, the ^1H T_2 value was obtained from the T_2 signal with experimental error of $\pm 5\%$. The result is the same as that of PVA gel.¹³ It can be said that the short T_2 component corresponding to the immobile region comes from the crosslinked region in the EVOH gels, the long T_2 component corresponding to the mobile region comes from the non-crosslinked region, the intermediate T_2 component with the intermediate mobility comes from the vicinity of the crosslinked region.

The ^1H T_2 values determined for the individual regions were plotted against the ethylene content. It is found that the ^1H T_2 values for the immobile, mobile and intermediate regions are gradually decreased with an increase in ethylene content. The increase of the ethylene content in EVOH samples in the gel state leads to reduction in molecular motion for the individual regions.

The fraction of each of the immobile, mobile and intermediate regions with different molecular motion were determined as a function of ethylene content. In the range of ethylene content less than 55%, the fractions of three kinds of regions with different mobilities are almost independent of ethylene content. In the ethylene content range greater than 55%, the fractions of the mobile region are rapidly decreased with an increase in ethylene content. On the other hand, the fractions

of the intermediate and immobile regions are largely increased with an increase in ethylene content. Their fractions are similar in value. This means that the fraction of the crosslinked region as formed by an addition of hydrophobic interaction between the ethylene parts to hydrogen bonds between the vinyl alcohol units is increased with an increase in ethylene content. From such a situation, the molecular motion for all of the three regions are more restrained with an increase in ethylene content.

2.1.6 Structure and Dynamics of Swollen Polymer Networks

The structural and dynamic characterization of swollen polymer networks has been one of the important research programs in polymer science. Samulski, et al. have elucidated the effect of orientation on residual quadrupolar splitting of deuterated solvents in swollen strained polyisoprene by ^2H NMR.⁵⁷ The quadrupolar splitting depends linearly on $\lambda^2 - \lambda^{-1}$ over a large range of the extension ratios (λ) and the degree of swellings. A phenomenological description based on a lattice model of the deformed, swollen network, which induces short-range nematic-like interactions successfully accounts for the observations. Also, the structural characterization of the other swollen networked polymers have been studied by ^2H NMR.^{58–60}

2.2 Approach by High-Resolution Solid-State ^{13}C NMR

It is well known that ^{13}C CP/MAS (cross polarization/magic angle spinning) NMR method obtains high-resolution solid-state NMR spectra of solid polymers and enhances the peak intensity of carbons in the immobile region.^{3,19–21} The CP efficiency is relatively high for carbons in rigid solid polymers. Polymer gels and polymers in the liquid crystalline state are relatively mobile. For this reason, care must be exercised to obtain ^{13}C CP/MAS NMR spectra because the ^{13}C signals of carbons in the mobile region may not appear due to the large reduction of the CP efficiency. It is often convenient to use MAS with strong ^1H decoupling, which leads to NOE (Nuclear Overhauser Effect), and without CP for obtaining the ^{13}C signals of carbons in the mobile state, for example, the PST (pulse saturation transfer)/MAS is often used, in which ^1H decoupling is carried out by using a number of pulses.²² MAS removes effectively weak dipolar coupling of carbons in the immobile state. In the case of polymer gels there exist mobile and immobile regions. For this, ^{13}C CP/MAS and PST/MAS methods are often used to get useful information about both regions. This leads to reasonable structural characterization of polymer gels.

If a conventional NMR rotor is used under high speed rotation (about 4 kHz), polymer gels and polymer liquid crystals come out of a conventionally sealed NMR rotor due to high speed rotation. From such a situation, it is convenient to use an NMR rotor sealed with an O-ring rubber, the use of which prevents loss of samples.¹⁴

2.2.1 Structural Characterization of Poly(Vinyl Alcohol) Gel

As mentioned above, amorphous-PVA gel is prepared by repeating freeze-thaw cycles from its aqueous solution. At the beginning of the gelation of the PVA aqueous solution, phase separation into polymer-rich and polymer-poor regions occurs

with a decrease in temperature. It is suggested that the gel formation is due to the formation of intermolecular hydrogen bonds.¹⁴ The structure and the amount of hydrogen bonds may play an important role for properties of PVA gel, and high-resolution solid-state ^{13}C NMR gives useful information about them.^{14,15} Figure 3 shows ^{13}C NMR spectra for PVA in the solution (a), gel (b–d) and solid (e) states as measured by solution and solid-state NMR. In conventional solution ^{13}C NMR spectrum for PVA gel shown in Figure 3(b), the ^{13}C signal for the CH carbon splits into three peaks assigned to mm, mr and rr triads. The signals for the CH and CH_2 carbons become broader as compared with those for PVA solution (Figure 3(a)). This is caused by the increase in dipole–dipole interactions due to a decrease in molecular motion. The ^{13}C PST/MAS NMR spectrum of the PVA gel shown in Figure 3(c) is similar to the solution NMR spectrum of Figure 3(b). However, the resolution of spectrum (c) is better than that of spectrum (b), because of a MAS and a high-power proton decoupling. NOE enhancement is used to obtain more intense ^{13}C signal using PST method.²² The PST method effectively enhances peak intensity for the mobile regions in samples as compared with CP and vice versa. This means that the mobile region in the PVA gel is observed in both spectra (b) and (c). The ^{13}C signal for the CH carbon of the solid PVA has three-split broad peaks in the ^{13}C CP/MAS NMR spectrum

Figure 3 ^{13}C NMR spectra for the PVA in the solution, gel and solid states as measured by solution and solid-state NMR methods. For solution NMR method: PVA/ D_2O solution (a) and PVA gel (b); for solid-state NMR method: PVA gel by PST/MAS (c) and CP/MAS (d), and solid PVA by CP/MAS (e)

as shown in Figure 3(e). Such a splitting is explained by the number of intramolecular hydrogen bonds formed among neighboring hydroxyl groups. Assuming that the ^{13}C chemical shift value for the CH carbon shifts to downfield by 6 ppm per one intermolecular or intramolecular hydrogen bond, the most deshielded peak (peak I) can be assigned to the CH carbon with two hydrogen bonds, the central peak (peak II) to the CH carbon with one hydrogen bond and the most shielded peak (peak III) to the CH carbon with no hydrogen bonds, respectively.²³ In the ^{13}C CP/MAS spectrum for the PVA gel as shown in Figure 3(d), the CH signal is composed of the three splitting peaks corresponding to the triad tacticity and the broad peaks as found in the solid PVA. This means that in this case both of the immobile and mobile regions of the PVA gel are observed by CP/MAS.

Figure 4 shows ^{13}C CP/MAS NMR spectra of the PVA gels with different polymer concentrations.¹⁴ The polymer concentrations of samples (a), (b), (c) and (d) are 9.1, 11.8, 13.8 and 35.0% (w/w), respectively. The intensities of the three-split peaks due to stereochemical configurations decrease and those of peaks I, II and III increase with a decrease in water fraction in the gel. The three peaks due to stereochemical configurations completely disappear in sample (d). The schematic crosslinked structure of PVA gel formed by intermolecular and intramolecular hydrogen bonds can be inferred from these spectra. The increase in the fraction of the immobile region and the formation of hydrogen bonds are promoted by the increase in the polymer concentration of the gel.

In order to clarify the dynamics of PVA gel, ^{13}C T_1 measurements were carried out.¹² The ^{13}C T_1 values for the mobile region in a PVA gel were determined by the inversion-recovery method combined with the PST/MAS technique and the immobile region was also determined using CP/MAS combined with Torchia's pulse sequence.⁵⁴ The T_1 values for the triads are

Figure 4 ^{13}C CP/MAS NMR spectra for PVA gels with different polymer concentrations. The polymer concentrations are (a) 9.1, (b) 11.8, (c) 13.8 and (d) 35.0% (w/w), respectively

smaller than those for peaks II and III. The immobile region corresponds to the CH carbons in the crosslinked regions formed by intermolecular and intramolecular hydrogen bonds in the gel, and the mobile ones to the regions away from the crosslinked regions that undergo fast molecular motion in the gel. The mobility of the network polymer in the PVA gel is restrained by hydrogen bonds and especially that of the crosslinked region is very low.

2.2.2 Gelation Mechanism of Poly(Vinyl Alcohol) in Aqueous Solution

PVA in aqueous solution forms a gel by undergoing freeze-thaw cycles. We have studied the structure and dynamics of PVA gels that were prepared using PVA samples with different microtacticity at some polymer concentrations under atmospheric pressure and high pressure by high-resolution solid-state ^{13}C NMR and ^1H pulse NMR.^{14,15,17} From these studies, we have demonstrated that the crosslinked region is formed by the formation of intermolecular hydrogen bonds. From such a situation, in this work we aim to measure high-resolution solid-state ^{13}C NMR spectra during the freeze-thaw cycles, and to elucidate the mechanism of gelation process for PVA in aqueous solution.

The degree of polymerization and the degree of saponification of amorphous PVA were 1700 and 99.9%, respectively. The PVA sample was dissolved into water at 120 °C using an autoclave. The polymer concentration was 10% (g dl⁻¹). The obtained PVA aqueous solution was cooled to room temperature and was contained in a cylindrical rotor with a rubber O-ring to prevent loss of water during the NMR measurements. Prior to NMR measurement, it was kept at room temperature for one month to reach a stable state.

^{13}C CP/MAS NMR spectra of PVA/water system during the freeze-thaw cycles are shown in Figure 5.²⁴ There are no signals in the ^{13}C CP/MAS NMR spectrum of aqueous PVA solution at 40 °C, because in the solution state the PVA chains are undergoing much faster molecular motion compared with a frequency of ^1H decoupling to be ca. 60 kHz used in this experiment, and so the CP efficiency is quite reduced. In the ^{13}C CP/MAS NMR spectrum of the PVA/water system in the freezing state at -30 °C, three peaks I, II and III for the CH signal, which come from the formation of hydrogen bonds as reported previously appear clearly.¹⁴ Peak I was assigned to carbons with two intermolecular or intramolecular hydrogen bonds, peak II to those with one intermolecular or intramolecular hydrogen bond, and peak III with no hydrogen bond. From this spectrum, it can be seen that some hydroxyl groups form hydrogen bonds at -30 °C as in the PVA gel. If the temperature is increased from -30 to 40 °C again, peak II at 71 ppm becomes broad and the three splitting peaks due to the triad configurations (mm, mr and rr) appear. This result shows that the molecular motion of PVA chains is decreased compared with that in the original solution state due to the formation of hydrogen bonds, and so the CP efficiency was enhanced. This means that the freeze-thaw process induces gel formation. In ^{13}C CP/MAS NMR spectrum of the PVA/water system in the 2nd frozen state, the three CH peaks are observed as clearly as the case in the 1st frozen state. The ^{13}C CP/MAS NMR spectra in the 3rd and 4th frozen states are almost identical. On the other hand, in the ^{13}C CP/MAS NMR spectrum of the PVA/water system in the thawing state

Figure 5 ^{13}C CP/MAS NMR spectra for PVA/water system under the freeze-thaw cycles

at 40°C , the intensity of peak II is gradually increased with an increase in the number of freeze-thaw cycles. In the 4th thawing state, peak II clearly appeared. This shows that the amount of hydrogen bonds in the course of the formation of the PVA gel is increased by repeating the freeze-thaw cycles.

These experimental results mean that the repeating of freeze-thaw cycles induces the gelation of the PVA/water system.

From these experiments, the mechanism of gelation for the PVA/water system was proposed as follows: in the solution state, there are no strong intermolecular hydrogen bonds and so the corresponding CH peak cannot be obtained using ^{13}C CP/MAS NMR method. In the frozen state, water is frozen and the PVA chains aggregate to form the polymer-rich domain. In the polymer-rich region, strong intermolecular hydrogen bonds may be formed and the corresponding CH peaks are clearly observed by ^{13}C CP/MAS NMR. By repeating the freeze-thaw cycles, the fraction of the polymer-rich regions is increased, and then the crosslinked region is formed, which consists of strong hydrogen bonds. Therefore, it can be said that the process of repeating the freeze-thaw cycles induce intermolecular hydrogen bonds and so is essential for the gelation of the PVA/water system.

2.2.3 Structure and Dynamics of Poly(γ -Methyl L-Glutamate) Gel

The properties of the polymer gels swollen in organic solvents are different from those of hydro-swollen gels. Crosslinked poly(γ -methyl L-glutamate) (PMLG) is prepared by the ester-amide exchange reaction using diaminododecane as a cross-linker and is swollen in trifluoroacetic acid (TFA) and CHCl_3 . The PMLG gel was studied by using high-resolution solid-state ^{13}C NMR spectroscopy.⁵⁵ A typical ^{13}C PST/MAS NMR spectrum of PMLG gel swollen in CHCl_3 is shown in Figure 6. The amide and ester carbonyl carbons of PMLG appear at 176.2 and 173.5 ppm, respectively. The C_α , OCH_3 , C_γ and C_β carbons appear at 57.6, 52.3, 31.3, and 26.1 ppm, respectively. The peak intensities of the side chain carbons is more intense than that of the main chain carbons.

Figure 6 ^{13}C PST/MAS NMR spectrum of PMLG gel swollen in CHCl_3

This means that the side chains are undergoing faster molecular motion compared with the main chain.

The ^{13}C chemical shifts of the individual carbons of PMLG gel are changed as a function of the TFA content (f_{TFA}) in a mixture of CHCl_3 and TFA. In the PMLG gel with CHCl_3 , the ^{13}C chemical shift values of the main chain amide $\text{C}=\text{O}$ and $\text{C}\alpha$ carbons are 176.2 and 57.6 ppm, respectively. The PMLG chain part of the crosslinked network takes the α -helix conformation as determined by reference data²⁵ of solid polypeptides at about 176 and 57 ppm. The amide $\text{C}=\text{O}$ and $\text{C}\alpha$ ^{13}C chemical shifts change transitionally from 176.5 and 57.6 ppm to 174.0 and 54.4 ppm, respectively, and so move upfield with an increase in TFA content. Such a transitional upfield shift shows that the main chain conformation of the PMLG network changes from the α -helix to the random coil form. The midpoint of the transition is at about $f_{\text{TFA}} = 0.15$. On the other hand, it is shown that in the side chain carbons the ester $\text{C}=\text{O}$ carbon moves downfield at the transition point, but the chemical shifts of the other carbons do not change clearly. The chemical shift of the main chain arises from the conformational change due to the formation of intramolecular hydrogen bond between the $\text{C}=\text{O}$ and $\text{N}-\text{H}$ in the main chain. The main chain chemical shift is considered to be very sensitive to the helix-coil transition. The large shift difference of the ester carbonyl carbons is due to the interaction with TFA. The ^{13}C chemical shifts of the other side chain carbons also show small changes at $f_{\text{TFA}} = 0.15$.

The degree of swelling for the PMLG gel is a function of f_{TFA} . The degree of swelling is transitionally decreased at $0-0.05 f_{\text{TFA}}$, is constant at $0.05-0.2 f_{\text{TFA}}$ and is gradually increased at $f_{\text{TFA}} > 0.2$. In the range $0.05-0.2$, the fraction of the random coil form is increased gradually with an increase in f_{TFA} and the degree of swelling is constant. The TFA content dependence of the ^{13}C T_1 of amide $\text{C}=\text{O}$ and ester $\text{C}=\text{O}$ carbons was observed at 20 and 40 °C. As the temperature decreases from 40 to 20 °C, the ^{13}C T_1 for the amide $\text{C}=\text{O}$ carbon increases and that of the ester $\text{C}=\text{O}$ carbon decreases. The molecular motion of the amide $\text{C}=\text{O}$ carbon is in the slow motion region ($\omega\tau_c \gg 1$, where ω is the resonance frequency) and that of the ester $\text{C}=\text{O}$ carbon is in the fast motion region ($\omega\tau_c \ll 1$) according to the BPP theory. The decrease in ^{13}C T_1 of the ester $\text{C}=\text{O}$ carbon in f_{TFA} from 0 to 0.05 shows that the decrease in molecular motion of side chain caused by a rapid shrinkage of the gel. In the range $f_{\text{TFA}} = 0.05-0.20$, ^{13}C T_1 of the amide $\text{C}=\text{O}$ carbon decreases with an increase in TFA content. This means that the molecular motion of main chains is increased in going from the α -helix to the random coil in the constant degree of swelling. On the other hand, the molecular motion of the side chains is not so affected by the helix-coil transition.

2.2.4 Structural and Dynamic Characterization of EVOH Gels

In the CP method, enhancement of the ^{13}C magnetization is effective for the relatively immobile solid-like region, but is greatly reduced for the mobile region in gels. For this, it is expected that ^{13}C CP/MAS NMR gives us dynamic information about gels in an addition to structural information. ^{13}C CP/MAS NMR spectra of EVOH gel samples were measured over a wide range of ethylene contents from 5 to 74% at room temperature.¹⁸ Only the intense background

signal in the ^{13}C CP/MAS spectra of EVOH gels with low ethylene contents from 5 to 48% appears. This results from the following reasons. At the measurement temperature, the gels are very soft, so the mobility of EVOH network chains becomes high. This leads to a large reduction of the CP efficiency. Thus, the background signal that comes from the polymer materials used in an NMR probe appears intensely in the spectrum. This was recognized from the CP/MAS experiment using an NMR rotor containing no sample. The ^{13}C CP/MAS spectra of EVOH samples with high ethylene content of 55 and 74% were obtained with a reasonable signal-to-noise ratio. It is found that the spectral patterns for the CH carbon of the V units and for the CH_2 carbon of the E and V units are greatly changed by varying the ethylene content. In order to obtain the sufficient CP efficiency for the immobile component of EVOH gels with low ethylene content, ^{13}C CP/MAS NMR spectra of EVOH gel with the ethylene content of 5% were measured with repetition time of 5 s by changing of the contact time in the range from 100 to 2000 μs . At long contact time the noncrystalline region that is undergoing slow molecular motion can be often observed.

The ^{13}C PST/MAS NMR spectrum of EVOH gel with ethylene content of 5% was shown in Figure 7(b). This spectrum is similar to solution-state ^{13}C NMR spectrum of EVOH, like the case of PVA gel.^{14,15} In the spectrum, the mm, mr and rr triad peaks for the CH carbon (in the 65–69 ppm region), and the m and r diad peaks for the CH_2 carbon (in the 45–48 ppm region) of V units in EVOH appear clearly. It can be said that the V units in the highly mobile region are observed by the PST/MAS NMR. On the other hand, ^{13}C CP/MAS NMR spectrum of its gel was measured under different conditions of the contact time of 1000 μs , the repetition time of 3 s and the accumulation number of 150 000 from the measurement condition used for the observed ^{13}C CP/MAS NMR spectra (see Figure 7(a)). In this spectrum, peaks I, II and III for the CH carbon of V units, which come from the immobile region, and the mr peak of the triad peaks (as appeared in the 65–69 ppm region) for the CH carbon, which comes from the mobile region appears clearly as shown in Figure 7(a). On the other hand, EVOH gel samples with higher ethylene-content become very hard, and thus ^{13}C CP/MAS NMR spectra of EVOH gels with the ethylene contents of 55 and 74% appear more clearly with a reasonable signal-to-noise ratio even at room temperature because the gels are solid-like, so their molecular motion is greatly restrained. This does not conflict with the pulse ^1H NMR results, in which the ^1H T_2 value of EVOH gels is decreased with ethylene content and the fractions of the mobile and intermediate regions (corresponding to the crosslinked and non-crosslinked regions, respectively) in EVOH gels with ethylene content larger than 55% are increased.

Next, we are concerned with temperature-variable ^{13}C CP/MAS NMR spectra of EVOH gels to obtain further dynamic information on the gels. ^{13}C CP/MAS NMR spectra of EVOH gels with ethylene content of 32% at 0 and 23 °C are shown in Figure 8. The ^{13}C CP/MAS NMR spectrum at 23 °C has very low signal-to-noise ratio and thus the intense background signal appears as a whole as shown in Figure 8(a). This means that the CP efficiency of the gels becomes insufficient by undergoing fast molecular motion at 23 °C, where these gel samples are very soft and thus mobility is high. As temperature is decreased, the individual peaks

Figure 7 67.8 MHz ^{13}C NMR spectra of EVOH gel with ethylene content of 5% at room temperature. (a) CP/MAS NMR spectrum and (b) PST/MAS NMR spectrum

in the spectrum (a) at 0 °C appear more clearly compared with the spectrum (b) at 23 °C. This is due to an increase in the CP efficiency by reduction of molecular motion at low temperature. The three peaks I, II and III for the CH carbon of the V units appear like the ^{13}C CP/MAS NMR spectra of solid EVOH samples.²⁹ Further, the EVOH copolymer gel prepared by using a mixture of DMSO and water as solvent is relatively harder compared with one prepared by using DMSO as solvent. This is because the intermolecular affinity between EVOH and mixture solvent of DMSO and water becomes much lower compared with that between EVOH and DMSO solvent, and then the hydrophobic and/or hydrophilic interactions between polymer chains are enhanced.

Thus, the EVOH copolymer with the ethylene content of 32% as prepared by using a mixture of DMSO and water as solvent becomes relatively solid-like. This leads to the ^{13}C CP/MAS NMR spectrum of the EVOH gel being well resolved with a reasonable signal-to-noise ratio, similar to solid EVOH.^{26–29} All peaks in these spectra can be assigned in the same way as already assigned in PVA gel¹⁴ and solid EVOH²⁹ as below.^{14,29}

Next, we are concerned with the spectral analysis. The spectral assignment was made according to the previous assignments on solid EVOH samples.²⁹ First, the assignment of the ^{13}C peaks of the CH carbon was made. The assignment of three peaks I, II and III of the CH carbon in EVOH gel with low ethylene content, which appeared at about 77, 71 and

Figure 8 67.8 MHz ^{13}C CP/MAS NMR spectra of EVOH gel with ethylene content of 32% at 0°C (a) and 23°C (b)

65 ppm, respectively, can be made according to the assignment of the CH peaks in PVA gel.¹⁴ Peak I comes from the formation of two intramolecular or intermolecular hydrogen-bonds, peak II from the formation of one intramolecular or intermolecular hydrogen-bond, and peak III from no hydrogen bond. On the other hand, in EVOH gel samples with high ethylene content, the ^{13}C chemical shift positions of peaks I and II are different from those in EVOH gel samples with low ethylene content. This is due to appearance of new configurational arrangements by the large amount of the ethylene units in the copolymers. From such a situation, according to the previous assignment we assign peak I to CH carbon of the V unit in EVE sequence as the major contribution in addition to two intramolecular or intermolecular hydrogen-bonded CH carbon of the V units as the minor contribution, and peak II from one intramolecular or intermolecular hydrogen bonded CH carbon of the central V unit in VVV sequences as the minor contribution.²⁹ Further, by analyzing the partially-relaxed spectra of EVOH gel (with the ethylene content of 5%) by using the Torchia method, it was found that each of three CH peaks I, II and III in EVOH gel remains even at longer delay time (≈ 15000 ms). This arises from the fact that peaks I, II and III in EVOH gel are frozen in molecular motion on the NMR timescale, because these three peaks comes from the crosslinking region in the gel. From the present results and the previous results in the sample of low ethylene content, it is concluded that the formation of hydrogen bonds between vinyl alcohol parts of EVOH contributes to gel formation.^{16,17}

Further, we are concerned with the peak assignment of the CH_2 carbon in EVOH gel with high ethylene content. The CH_2 peaks at 30 and 33 ppm come from the asterisked central CH_2 carbons in both of the $-\text{CH}_2-\text{CH}_2-\text{CH}_2^*-\text{CH}_2-\text{CH}_2-$

unit and $-\text{CH}_2-\text{CH}_2-\text{CH}_2^*-\text{CH}_2-\text{CH}_2-$ unit with and without fast exchange between the *trans* and *gauche* conformations, respectively. The CH_2 peak at 30 ppm decays more rapidly than the CH_2 peak at 33 ppm. This arises from the fact that the CH_2 carbons of the ethylene units with the *trans* zigzag conformation in the crystalline region, which appear at 33 ppm, are frozen on the NMR timescale. On the other hand, the CH_2 carbons in the non-crystalline region, which appear at 30 ppm, are undergoing fast exchange between the *trans* and *gauche* conformations at room temperature.^{30,31} In this case, in EVOH samples with high ethylene content, the gel may be formed in the crystalline region by hydrophobic interactions between the ethylene units of EVOH.

2.2.5 Structural Characterization of Poly(Methacrylic Acid) Gel

The structural and dynamic characterization of poly(methacrylic acid) gel with water as a function of degree of crosslinking was carried out through the observation of high-resolution solid-state ^{13}C NMR spectra by using ^{13}C PST/MAS NMR.⁴¹ ^{13}C PST/MAS NMR spectra of PMAA gels with $Q = 3.4, 21.7$ and 105.8 are shown in Figure 9.⁵⁶ It is seen that high-resolution spectra are obtained. This indicates that the efficiency of MAS to obtain high resolution spectrum is very high for polymer gel systems. The peaks of the PMAA gel can be assigned to the $\text{C}=\text{O}$, CH_2 , quaternary C, and CH_3 carbons from downfield. Each of the $\text{C}=\text{O}$ and CH_3 carbon signals is split into three peaks due to the triad configurations of PMAA. These peaks are designated by the $\text{C}=\text{O}$ (rr:182.5 ppm), $\text{C}=\text{O}$ (mr:181.5 ppm), $\text{C}=\text{O}$ (mm:180.8 ppm), CH_3 (mm:22.3 ppm), CH_3 (mr:19.8 ppm)

Figure 9 ^{13}C PST/MAS spectra of PMAA gels with $Q = 105.8$ (a), 21.7 (b) and 3.4 (c) at 300 K

and CH_3 (mm:18.2 ppm). The peak intensity ratio of these triad signals corresponds to the triad fraction. From the CH_3 signals, the triad fraction is evaluated as rr:mr:mm = 67.4 : 27.1 : 5.5%. The ^{13}C chemical shift values for the PMAA gels are independent of Q . This means that there is no specific effect on the ^{13}C chemical shift by changing Q .

From the ^{13}C T_1 measurements, it was found that molecular motion of the side chain carbons is in the extremely narrowing region in the BPP theory and that of the main chain carbons is in the slow motion region, and an increase in the degree of crosslinking in the PMAA gel leads to restraint in the segmental motion of the network polymer.

2.2.6 Structural and Dynamic Characterization of Poly(L-Glutamates) with N-Alkyl Side Chains in the Thermotropic Liquid Crystalline State

It is known that in a series of α -helical poly(L-glutamates) with n -alkyl side chains of various lengths, n -alkyl side chains longer than $n = 10$ form a crystalline phase composed of paraffin-like crystallites together with an α -helical main chain packing into a characteristic layer structure. The polymers form thermotropic liquid crystals by the melting of the side chain crystallites. The structural and dynamic behavior of the polymers over a wide range of temperatures in going from the solid state to the thermotropic liquid crystalline state has been elucidated by variable temperature ^{13}C CP/MAS NMR.^{33,34} It has been demonstrated that the ^{13}C chemical shifts of the main chain amide carbonyl and $\text{C}\alpha$ carbons in polypeptides are conformation-dependent and thus the main chain conformation can be determined by the ^{13}C chemical shift position of the

main chain carbons.²⁵ Also, like polypeptides the conformation of long n -alkyl side chains can be determined by the ^{13}C chemical shift position.⁴⁶

In Figure 10 the ^{13}C CP/MAS NMR spectra of poly(γ - n -octadecyl L-glutamate) (POLG) with long n -alkyl $[-(\text{CH}_2)_{17}\text{CH}_3]$ side chains are shown over a wide range of temperatures from -40 to 230°C . Assignments for peaks are straightforward as indicated in the spectra. The ^{13}C chemical shift values of the amide carbonyl and $\text{C}\alpha$ carbons are 176.2 and 57.4 ppm, respectively. These values are characteristic of the right-handed α -helix conformation of the main chain of POLG. On the other hand, the assignment for peaks of n -alkyl side chains of POLG is performed by the using reference data on n -alkanes. At temperatures from -40 to 40°C , the ^{13}C chemical shift values of the inner CH_2 carbons of the side chains are 33 ppm. This means that the inner CH_2 carbons of the side chains take an all-*trans* zigzag conformation in the orthorhombic form. At temperatures above 50°C , the ^{13}C chemical shift value moves transitionally upfield by ca. 3 ppm. This means that n -alkyl side chains melt like liquid n -alkanes and then the fast exchange between the *trans* and *gauche* conformations occurs. Such an upfield shift occurs according to equation (1)

$$\delta_{\text{obs}} = \delta_o - 2\gamma f_g \quad (1)$$

where δ_{obs} and δ_o are the observed ^{13}C chemical shift and the ^{13}C chemical shift for the *trans* conformation, f_g is the fraction of the *gauche* conformation, and γ is attributed to the chemical shift difference (ca. 5.3 ppm) between the *trans* and *gauche* conformations.³⁰ At temperatures above 50°C , this polymer forms a thermotropic liquid crystalline state.

In Figure 10 it is shown that the broadening phenomenon for peaks of the main chain carbons can be explained on the basis of the consideration that when the orientation rate of the main chain in the liquid crystalline state is close to a frequency corresponding to the amplitude of the proton decoupling field (about 60 kHz for this experiment), the efficiency of the proton decoupling is considerably reduced and the line width becomes the maximum. Thus, it can be said that the main chain is undergoing reorientation at a frequency of ca. 60 kHz in the temperature range from 50 to 90°C .

In poly(L-glutamate) with long oleyl $[-(\text{CH}_2)_8\text{CH}=\text{CH}(\text{CH}_2)_7\text{CH}_3]$ side chains which contain a double bond (POLLG), the melting of the side chain crystallites is at a much lower temperature than that of POLG. This polymer forms thermotropic liquid crystals from lower temperature.⁴⁵ The spectral behavior is very similar to POLG.³⁴

2.3 Approach by Pulse Field-Gradient Spin-Echo ^1H NMR

2.3.1 Pulse Field-Gradient Spin-Echo ^1H NMR Measurements

In order to determine the diffusion coefficient of solvent and probe molecules in a gel, pulse field-gradient spin-echo (PFGSE) NMR is used. This method is very powerful.^{5,35,36} However, if one wants to determine relatively small diffusion coefficients with high accuracy, a strong strength of the field gradient must be used. We have designed two kinds of PFGSE NMR probe systems of generating the strength of the field

Figure 10 ^{13}C CP/MAS NMR spectra of poly(γ -octadecyl L-glutamate) over a wide range of temperatures

gradient pulse of 7.8 T m^{-1} and 22.8 T m^{-1} .³ This leads to a determination of the diffusion coefficient on the order of $10^{-14} \text{ m}^2 \text{ s}^{-1}$. As the PFGSE pulse sequence, two field gradient pulses are added to the ($\pi/2$ pulse $-\tau - \pi$ pulse) sequence, in which the first field gradient pulse is added at the mid position between the $\pi/2$ and π pulses (that is, at the position of τ^* after the $\pi/2$ pulse), and the second at the position of τ^* after the π pulse.³⁷

The relationship between the echo signal intensity and pulse field gradient parameters is given by equation (2)

$$A(\delta)/A(0) = \exp[-\gamma^2 G^2 D \delta^2 (D - \delta/3)] \quad (2)$$

where $A(\delta)$ and $A(0)$ are echo signal intensities at $t = 2\tau$ with and without the magnetic field gradient pulse, respectively, whose length is δ . τ is the pulse interval, γ the gyromagnetic ratio of the proton ($\gamma = 2.675 \times 10^8 \text{ rad T}^{-1} \text{ s}^{-1}$), G the field gradient strength, D the self-diffusion coefficient, and Δ the gradient pulse interval. The echo signal intensity was measured as a function of δ . The plot of $\ln[A(\delta)/A(0)]$ against $\gamma^2 G^2 \delta^2 (\Delta - \delta/3)$ gives a straight line with a slope of $-D$. Therefore, D can be determined from the slope. The τ , Δ and δ values employed in these experiments were 10, 10 and 0.001–0.12 ms, respectively. The D value of $2.5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ for water at 303 K was used as the calibration of the field gradient strength.³ The experimental error for the D value is estimated to be less than ca. 5%.

2.3.2 Diffusional Behavior of Synthetic Polymer Gels

2.3.2.1 Diffusional Behavior of Water in Poly(methacrylic acid) Gels

In order to investigate changes in the translational motion of water contained in the poly(methacrylic acid) (PMAA) gel by a change in the degree of crosslinking, the diffusion coefficient of water molecules ($D_{\text{H}_2\text{O}}$) in PMAA gels with the degree of swelling $Q = 3.4\text{--}105.8$ was determined by PFGSE ^1H NMR method at 300 K.³⁸ As seen from this table, $D_{\text{H}_2\text{O}}$ increases as Q is increased. This means that an increase in Q leads to an increase in mobility of water molecules. If the $D_{\text{H}_2\text{O}}$ increases are plotted against $Q^{1/3}$, it is seen from Figure 11 that $D_{\text{H}_2\text{O}}$ increases linearly from 1.37×10^{-9} to $2.19 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ with increasing $Q^{1/3}$.³⁹ This shows that the translational molecular motion of water molecules in the PMAA gel increases with an increase in the degree of swelling. The $D_{\text{H}_2\text{O}}$ value of neat water at 300 K is $2.5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. Therefore, it can be said that the translational molecular motion of water molecules in the gel is more restrained compared with that of neat water by the intermolecular interactions with the polymer network.

We are concerned with the reason why there exists a linear relationship between the $D_{\text{H}_2\text{O}}$ and $Q^{1/3}$. The volume for the gel that contains network polymer and water may be associated with $Q^{1/3}$. Assuming that the volume for the gel is a cube with the length of an edge being r , the degree of swelling for the

Figure 11 Plots of diffusion coefficient of water ($D_{\text{H}_2\text{O}}$) in PMAA gel against $Q^{1/3}$ at 300 K

gel is rearranged as equation (3)

$$Q = M_{\text{swollen}}/M_{\text{dry}} = (\rho_{\text{swollen}} \cdot V_{\text{swollen}})/M_{\text{dry}} = (\rho_{\text{swollen}}/M_{\text{dry}})r^3 \quad (3)$$

where ρ_{swollen} is the density of swollen polymer gel and V_{swollen} the volume of swollen polymer gel. M_{dry} is a constant. By rearranging equation (3), we obtain equation (4)

$$r = (M_{\text{dry}}/\rho_{\text{swollen}})^{1/3} Q^{1/3} \quad (4)$$

If Q is changed as a function of the degree of crosslinking of the gel, ρ_{swollen} does not change greatly (at 300 K $\rho_{\text{swollen}} = 1.001 \text{ g cm}^{-3}$ at $Q = 3.4$ and $\rho_{\text{swollen}} = 0.997 \times 10^3 \text{ Kg m}^{-3}$ at $Q = 106$). Therefore, it can be said that the length of an edge of the volume of the gel (r) is proportional to $Q^{1/3}$. This means that r of the volume containing a constant amount of network polymer increases with an increase in $Q^{1/3}$ and so the size of the polymer network in the gel expands the intermolecular distance between water molecules increases. For this, the molecular motion of molecules increases with an increase in $Q^{1/3}$. From the linear relationship between the $D_{\text{H}_2\text{O}}$ and $Q^{1/3}$, it can be said that the molecular motion of water depends on intermolecular distance.

2.3.2.2 Diffusional of Water and Poly(Ethylene Glycol) in Poly(Dimethylacrylamide) Gels

The diffusion coefficients of HDO (D_{HDO}) and poly(ethylene glycol) (PEG) contained in poly(dimethylacrylamide) (PDMAA) gel were determined by the PFGSE ^1H NMR method as described above at 303 K varying Q and molecular weight (M_w) of PEG.⁴⁰ The D_{HDO} values obtained were plotted against Q as shown in Figure 12. As seen from this figure, D_{HDO} increases as Q is increased, and is almost independent of M_w of PEG contained in the gel. The change of D_{HDO} in the small Q region is much larger than that in the large Q region. The D_{HDO} value in the large Q region asymptotically approaches that for HDO in neat D_2O ($2.22 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$). Therefore, it can be said that the intermolecular interaction between water and polymer network, of which the strength depends on the size of a network, restrains translational motion of the water. There is almost no effect on the molecular motion

Figure 12 Dependence of the diffusion coefficient of water molecules (D_{HDO}) on the degree of swelling (Q) in a PDMAA gel containing PEG with $M_w = 4250$ ($\square$), 10890 ($\blacktriangle$) and 20000 ($\circ$) at 303 K

of HDO by the change of M_w of PEG, indicating that the diffusion of HDO is independent of M_w of PEG.

We can understand these results by using the modified free volume theory proposed by Fujita.⁴¹ The diffusion coefficient is related to the friction ζ by the equation $D = kT/\zeta$, where k is the Boltzmann constant and T the absolute temperature. The dependence of ζ on solvent concentration is expressed as an exponential function of the fractional free volume f . Thus, we have equation (5)

$$D_{\text{HDO}} = D_{\text{HDO}}^0 \exp[Q^{-1}/(Q^{-1}f_{\text{solv}} - f_{\text{solv}}^2/\beta)] \quad (5)$$

The dynamic behavior of a probe polymer in a gel can be analyzed by the ratio of the screening length of polymer network to the dimensional size of PEG. It is shown that the diffusion of a particle in semi-dilute polymer solution and in a polymer gel is obeyed by the relation shown in equation (6)

$$D/D^0 = \exp(-\kappa R) \quad (6)$$

where D^0 is the diffusion coefficient of an isolated particle, R the radius of a particle and κ^{-1} the dynamical screening length of the polymer chain. When $D/D^0 = \kappa^{-1}$, κ^{-1} is equivalent to R . This relation has also been employed for elucidating the self-diffusion of random-coil polymers in solution and gel, in which the values of κ^{-1} are large enough for probe polymers to have the same motion as for a hard sphere. In these cases, the interchain hydrodynamic interactions more significantly contribute to the diffusion process compared with the topological constraints. For this, the hydrodynamic radius of a probe polymer can be replaced by R . When the topological constraints cannot be neglected compared with the interchain hydrodynamic interactions, D s becomes larger than the value expected from equation (6). When the diffusion coefficient of an isolated PEG (D_{PEG}^0) is determined from the diffusion coefficient of PEG in aqueous dilute solution ($D_{\text{PEG}}^{\text{soln}}$), it is necessary to take into account the change of local friction of polymer, which is estimated by the change for the

diffusion coefficient of the solvent. Then, D_{PEG}^0 is given by equation (7)

$$D_{\text{PEG}}^0 = D_{\text{PEG}}^{\text{soln}} / (D_{\text{HDO}}^{\text{neat}} / D_{\text{HDO}}) \quad (7)$$

where $D_{\text{HDO}}^{\text{neat}}$ is the diffusion coefficient of HDO in D_2O . In this work, the diffusion of water and PEG in a PDMAA gel has been analyzed by the above mentioned equations (6) and (7).

2.3.2.3 Diffusion Coefficient of HDO in a PDMAA Gel

We can more clearly understand the dynamic behavior of water in the gel system using equation (5) obtained from modified free volume theory.^{31,41} The solid curve obtained from a least-squares fitting to the experimental data using equation (5) is shown in Figure 12. The theoretical curve agrees well with the experimental data. From this result, the diffusion coefficient for HDO in infinite swollen gel ($Q \rightarrow \infty$) is obtained to be $D_{\text{PEG}}^0 = 2.16 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, which is lower than HDO in neat D_2O ($2.22 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$). This means that the diffusion coefficient for HDO in neat D_2O is different from the Q -extrapolated value to infinity given by the modified free volume theory for the diffusion concentration dependence. The diffusion coefficient for an isolated HDO molecule in bulk PDMAA ($Q \rightarrow 1$) obtained from Figure 12 was $2.5 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. It is seen that the translational motion of isolated water in bulk polymer is more strongly restrained compared to that in the gel. Further, it can be said that the rapid decrease of D_{HDO} in the small Q region can be explained by the decrease in free volume.

2.3.2.4 Diffusion Coefficient of PEG in a PDMAA Gel

In order to investigate the translational motion of PEG contained in PDMAA gel as a probe polymer, the diffusion coefficient of PEG (D_{PEG}) was determined by PGSE ^1H NMR at 303 K varying Q and M_w of PEG contained in the gel. It was found that D_{PEG} increases as Q is increased and also depends on M_w of PEG. The D_{PEG} value in the gel is smaller than that at 1% wt aqueous PEG solution ($D_{\text{PEG}}^{\text{soln}}$) at 303 K. Therefore, it can be said that the translational motion of PEG in the gel is more restrained by large intermolecular interaction with polymer network as compared with PEG in aqueous solution and that PEG with higher M_w is more strongly restrained.

Next, we are concerned with the relationship between the degree of restraint in molecular motion of PEG in the gel and the ratio of the screening length of polymer network to the size of PEG.⁴⁰ The dynamic behavior of PEG in the gel can be analyzed by using equation (6). The relationship between the dynamic screening length (κ^{-1}) and the concentration of network polymer (c) or the degree of swelling (Q) is expressed by equation (8)

$$\kappa^{-1} = c^u = Q^{-u} \quad (8)$$

where u may be a constant in the range from -0.5 to -1.0 , but depends largely on the polymer species. Substitution of equations (6) and (7) into equation (8) gives equation (9)

$$D_{\text{PEG}} D_{\text{HDO}}^{\text{neat}} / D_{\text{PEG}}^{\text{soln}} D_{\text{HDO}} = \exp(-Q^u R). \quad (9)$$

Figure 13 Plots of $\ln[(-\ln(D_{\text{PEG}} D_{\text{HDO}}^{\text{neat}} / D_{\text{PEG}}^{\text{soln}} D_{\text{HDO}})) D_{\text{PEG}}^{\text{soln}}]$ against $\ln Q$ at 303 K. M_w s of PEGs used are 4250 ($\square$), 10 890 ($\blacktriangle$) and 20 000 ($\circ$)

It is convenient to rewrite it in the form shown in equation (10)

$$\ln \left(-\ln \frac{D_{\text{PEG}} D_{\text{HDO}}^{\text{neat}}}{D_{\text{PEG}}^{\text{soln}} D_{\text{HDO}}} \right) = u \ln Q + \ln R. \quad (10)$$

In Figure 13, the $\ln[(-\ln(D_{\text{PEG}} D_{\text{HDO}}^{\text{neat}} / D_{\text{PEG}}^{\text{soln}} D_{\text{HDO}})) D_{\text{PEG}}^{\text{soln}}]$ value calculated using the experimental data is plotted against $\ln Q$. A straight line with a slope of -0.71 is obtained and so $u = -0.71$. Therefore, we have $\kappa^{-1} \sim Q^{0.71} = c^{-0.71}$. Depending on the nature of network and solvent, there are a variety of theoretical calculations for the concentration dependence of the dynamical screening length. de Gennes proposed that for flexible polymer chains in a gel with good solvent the relationship $\kappa^{-1} \sim c^{-0.71}$ is obtained.⁵⁴ This prediction is in agreement with the above experimental results.

2.3.2.5 Diffusion Behavior and Intermolecular Hydrogen-Bond Between Probe Polymer and Network Polymer in (N,N-Dimethylacrylamide–Acrylic Acid) Copolymer Gels

Molecular dynamics of a probe polymer is strongly affected in polymer gel systems with various kinds of intermolecular interactions between the probe polymer and the network polymer, such as hydrogen-bonding interactions, hydrophobic interactions, Coulomb interactions, etc. For example, by adding aqueous PEG solution to aqueous poly(acrylic acid) (PAA) solution the complex between PEG and PAA is formed by the formation of hydrogen bonds between the oxygen atoms of PEG and the carboxyl groups of PAA. Also, in PDMAA hydrogel the complex between PEG and PDMAA is formed by the same interaction. The justification for the formation of such complexes has been carried out by macroscopic methods such as viscosity measurements for solutions and mass measurements for gels. Nevertheless, in order to clarify more clearly such intermolecular interactions between probe polymer and network polymer in the gel systems, systematic studies by microscopic methods such as NMR spectroscopy are needed.⁴³

2.3.2.6 Diffusion Coefficient of HDO in (DMAA-AA) Copolymer Gels

The diffusion coefficients of HDO (D_{HDO}) contained in PDMAA gels, PAA gels and (DMAA-AA) copolymer gels with PEG were determined by PGSE ^1H NMR at 303 K varying Q and f_{AA} .⁴⁴ The D_{HDO} values obtained were plotted against Q . From this plot, it was found that the D_{HDO} increases as Q is increased. The molecular motion of HDO is not affected by a change of f_{AA} in the region of $f_{\text{AA}} < 0.9$. This means that the translational motion of the HDO molecule increases as the size of the network becomes larger. The dynamic behavior of solvent in a gel can be analyzed by the modified free volume theory. As described above D_{HDO} in a PDMAA gel can be expressed by equation (9). From a least-squares fit to the experimental data for PDMAA gels using equation (9), we can determine D_{HDO}^0 , f_{solv} and β to be $2.16 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, 0.178 and 0.079, respectively. The calculation by using equation (6) and parameters obtained for PDMAA gels, agrees well with the experimental data obtained for (DMAA-AA) copolymer gels with f_{AA} value less than 0.9. This indicates that the diffusion of HDO is independent of the concentration of carboxylic acid group in this region. D_{HDO} s in PAA gels are larger than those in (DMAA-AA) copolymer gels. This may be because the concentration of H^+ ions dissociated from carboxylic acid groups in PAA gels, which diffuse faster than HDO, is higher than that in (DMAA-AA) copolymer gel.

2.3.2.7 Diffusion Coefficient of PEG in (DMAA-AA) Copolymer Gels

In order to investigate the translational motion of PEG contained in PDMAA gels and PAA gels as probe polymer, the diffusion coefficient of PEG (D_{PEG}) was determined by PGSE ^1H NMR at 303 K varying Q of the gel.⁴⁴ The D_{PEG} value in PDMAA gel is smaller than that in aqueous 1% wt PEG solution (dashed line), and increases as Q is increased. From the plot of $\ln(-\ln(D/D_0))$ against $\ln Q$, it was shown that this behavior is followed by $D/D_0 = \exp(-Q^2 R)$, and is similar to that mentioned above. Therefore, it can be said that the translational motion of PEG in PDMAA gel is restrained by hydrodynamic interaction with polymer network. This means that polymer network is working as only a spatial obstruction for the displacement of PEG. The D_{PEG} value in PAA gels is much smaller than that in PDMAA gel. This suggests that the loose complex of PEG and PAA network is formed by intermolecular hydrogen-bond interactions between the oxygen atoms of PEG and the carboxyl groups of PAA.⁴⁹ By addition of a small amount of HCl into the solution for the gel to be 0.15 mM in concentration, the gel shrinks and D_{PEG} is decreased. The complexation arises from intermolecular hydrogen-bond interaction between oxygen atoms of PEG and the carboxylic groups of AA units in the undissociated state as shown below. Therefore, it can be said that the addition of HCl leads to an increase in the amount of undissociated carboxylic groups and so enhances the formation of the complex and induces the shrinkage of the gel. This leads to slow diffusion of PEG. The addition of amine decreases the amount of dissociated carboxylic group and so inhibits the formation of the complex. This leads to fast diffusion of PEG and the swelling of the gel.

2.4 Diffusion Behavior of Polypeptide Gels

NMR methods involving pulsed magnetic field gradients provide one of the most attractive techniques for studies of molecular dynamics in polypeptide solution and gel systems. In particular, PFGSE NMR has been an invaluable tool in determining the anisotropic structures of polypeptide lyotropic liquid crystalline phase. Almost two decades ago, the first lateral diffusion coefficient of an amphiphile in a lamellar liquid crystalline phase was measured directly using PFGSE NMR. In recent years, the range of applications of NMR diffusion techniques has been growing rapidly, due to the great improvements in the NMR equipment for the diffusion microscopy. The diffusion behavior of solvent molecule in polypeptide gel system with α -helix-random coil transition, and on the diffusion behavior of solvent and probe n -alkanes molecules in polypeptide gel system with highly-oriented structures is introduced.

2.4.1 Diffusion Behavior of Solvents in Unoriented Polypeptide Gels

In high-resolution solid-state ^{13}C NMR experiments on cross-linked poly(γ -methyl L-glutamate) (PMLG) gel, we have found that the conformation of cross-linked PMLG with a mixture of chloroform (CHCl_3) and trifluoroacetic acid (TFA) largely depends on the solvent composition. The increase of volume fraction of TFA (f_{TFA}) in a mixture of CHCl_3 and TFA induces the α -helix-random coil transition of the main chain of cross-linked PMLG. CHCl_3 and TFA are sometimes so-called 'helix' and 'coil' solvents, respectively. It is important for gel science in polypeptide gel systems to elucidate how the translational motion of these solvents is affected when the main-chain of PMLG changes from the α -helix form to the random coil form. In such systems, the diffusion of solvent molecules contained in the polypeptide gel system strongly depends on the dynamics of polypeptide chains. As demonstrated above, PFGSE NMR gives useful information about the diffusion process of polymer gel system. From such a background, the dynamics of solvents in cross-linked PMLG gel with a mixture of CHCl_3 and TFA on going from the α -helix form to the random coil form through the diffusion coefficients were determined by PFGSE ^1H NMR.⁴⁵

2.4.2 Diffusion Behavior of Solvent and Probe-Molecules in Highly-Oriented Polypeptide Gels

As is well known, poly(γ -benzyl L-glutamate) (PBLG) forms the lyotropic liquid crystalline state in good solvents such as dichloromethane, dioxane, chloroform, etc. and when the PBLG liquid crystalline solution is placed in a strong magnetic field, the main chain can be oriented in the direction of the magnetic field. The molecular motion of solvent and PBLG in the liquid crystalline solution is considerably influenced by intermolecular interactions. By reacting highly-oriented PBLG chains with a cross-linker in a strong magnetic field, cross-linked PBLG gel with the highly-oriented α -helical chains is assumed to be formed.⁴⁶ We are interested in the problem of the diffusion process of solvent and n -alkanes with relatively extended conformation in the gel with anisotropic structure. The interest lies in the fact that n -alkanes are basic

molecules for understanding structure and dynamics of linear polymer chains.

According to the work on the orientation of *n*-alkanes in PBLG liquid crystalline solution by ^1H NMR, in which PBLG chains are highly oriented, *n*-alkanes being guest molecules are highly oriented to the magnetic field of an NMR magnet with the relatively extended conformation along the α -helical PBLG chains.⁴⁷ Also, as elucidated by NMR *n*-alkanes in the rotator phase take an extended conformation, which are rotating rapidly around the long axis. Thus, the diffusion coefficients for the directions parallel and perpendicular to the long axis differ.^{36,37}

With this as a background, cross-linked PBLG gels with highly-oriented α -helical chains are prepared. The diffusion coefficient of the solvent and *n*-alkanes in the gel for the directions parallel and perpendicular to the α -helical PBLG axis by using the PFGSE ^1H NMR method with strong field-gradient strength has been studied. In the liquid crystalline and gel states, the orientation of the PBLG chains can be determined by using high-resolution solid-state ^{13}C NMR.

2.4.3 Diffusional Process of Water in Starch Gels

The diffusional phenomena of compartmentalized water such as water in biological cells reflect the size and shape of the microstructure of the compartments and permeability of the barriers. The diffusion coefficients of water in corn starch gels, various wheat starch pastes and potato starch gels were measured.^{48–50} The diffusion coefficient (D_0) of water, the permeability of the barriers and the size of microstructure in potato starch gels have been determined by using the equation of restricted diffusional motion. The D_0 value is gradually decreased with an increase in the starch concentration and approaches a constant value of about $1.0 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. If the diffusion comes from restricted diffusion by a structural barrier (a), the interbarrier diffusion coefficient may be equal to the diffusion coefficient of pure water. These results show that the diffusion coefficient is affected by obstruction and hydration effects by polymers that are dispersed in the water compartments. The compartmentalized water experiences higher viscosity and/or a longer lifetime in the hydration sphere of starch chains. The permeability is gradually decreased with an increase in the starch concentration and is reached a constant value at more than 30% concentration. This shows that the polymer network of barriers is more dense in the gels at higher concentration. This does not conflict with general experimental results that the higher is the starch concentration, the stiffer is corresponding gel. The value of the distance between the neighboring barriers is independent of the starch concentration for fresh gels. The increase in polymer concentration causes an increase in the density of barriers until the latter reaches its limiting value. The density of barriers reaches the limit value (at a concentration between 33.3 and 37.9%), further increase in the concentration causes a decrease in the a value. From these experimental results, the fresh starch gel structure may be pictured that some of the polymers aggregate to make the starch network of the gel and the remaining polymers, and/or parts of polymer chain, are free from the starch network and function as a solute in water compartmentalized by the network.

2.5 Diffusion in Poly(γ -*n*-octadecyl L-glutamate) and Poly(γ -oleyl L-glutamate) (POLLG) in the Thermotropic Liquid Crystalline State

In order to elucidate more deeply dynamics of the polypeptides in the thermotropic liquid crystalline state, it is important to have some knowledge of the magnitude of the diffusion coefficient and the anisotropy of the diffusion for the directions parallel and perpendicular to the α -helical chain axis. For measurements of the diffusion coefficients, it has been demonstrated that PFGSE ^1H NMR can provide useful information to elucidate the diffusion process of solvents for polypeptides in the liquid crystalline state, in addition to polymer gel systems and *n*-alkanes in the rotator phase like the liquid crystalline state.⁵¹

To this end, the isotropic and anisotropic diffusion coefficients of the POLG chain in an highly-oriented sample prepared in the magnetic field produced by 500 MHz NMR equipment and the isotropic diffusion coefficients of the POLLG chain in the thermotropic liquid crystalline state were measured over a wide range of temperatures.⁵² Further, T_2 of the side chain protons of POLG and POLLG were measured over a wide range of temperatures, and then the dynamics of the side chains were elucidated.

The highly-oriented POLG sample was prepared by the following procedure:

1. POLG was dissolved in 1,2-dichloroethane in an NMR glass tube to form the lyotropic liquid crystalline state.
2. the sample was placed in an NMR glass tube with a diameter of 5 mm and thence into the magnetic field of a 500 MHz NMR magnet for 60 hours until the POLG chains were aligned parallel to the magnetic field. The direction of the magnetic field was along the long axis of the NMR tube. After the full orientation of the polypeptide chains, solvent was vaporized from the NMR tube and then the highly-oriented film was obtained on the wall of the NMR tube. The complete orientation of the POLG chains in the film was confirmed by cross-polarized microscopy.

2.5.1 Diffusional Behavior and Dynamics of POLG and POLLG

In the spin-echo ^1H NMR spectra of POLG in the liquid crystalline state at 80 °C, an asymmetric relatively sharp signal appears, which has a chemical shift position (0.9 ppm) at the peak. This peak can be straightforwardly assigned to the methyl protons in the side chains. The upper shoulder peaks may be assigned to the methylene protons in the side chains. The peaks that come from the main chain protons such as α -CH proton and amide proton do not appear within the measurement temperature range. This is due to dipolar-broadened signal because of anisotropic molecular motion slow compared to the dipolar frequency, $\omega_0/2\gamma$. However, the spin-echo ^1H NMR spectra of POLLG are similar to those of POLG. Thus, the peak assignment can be made by comparison.

The plots of $\ln[A(\delta)/A(0)]$ against $\gamma^2 G^2 \delta^2 (\Delta - \delta/3)$ for the above-mentioned peak (at ca. 0.9 ppm) in the PFGSE ^1H NMR spectra of POLG and POLLG, become straight lines (not shown here). This shows that the diffusion of POLG and POLLG consists of a single component during the observation time. Hence, the diffusion coefficients for POLG and POLLG

Figure 14 Temperature dependence of the diffusion coefficients of POLG chains in the direction parallel and perpendicular to the α -helical axis magnetic field and the isotropic diffusion coefficients ($D_{\text{iso}} (= D_{\parallel} + 2D_{\perp})/3$), and the isotropic diffusion coefficients of POLLG within the temperature range from 30 to 80 °C

considered here were determined from the slope of the straight line as seen from equation (1).⁵²

The diffusion coefficients of the rod-like polypeptide chains for the directions parallel ($D_{\parallel}$) and perpendicular ($D_{\perp}$) to the α -helical chain axis were determined, and the isotropic diffusion coefficient (D_{iso}) was estimated by an average of the determined $D_{\parallel}$ and $D_{\perp}$ values as $(D_{\parallel} + 2D_{\perp})/3$ (Figure 14). As the temperature is increased from 60 to 80 °C, the $D_{\parallel}$ values of POLG in the liquid crystal state increase monotonically from 5.48×10^{-11} to $1.11 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ and, the $D_{\perp}$ values increase monotonically from 1.41×10^{-11} to $8.87 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. The determined $D_{\parallel}$ and $D_{\perp}$ values at 60 °C are 5.48×10^{-11} and $1.41 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, respectively, and those at 80 °C are 1.11×10^{-10} and $8.87 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, respectively. The diffusion of POLG in the thermotropic liquid crystalline state is anisotropic. The diffusion of the polypeptide along the long α -helical chain axis at 60 °C is roughly four times faster than that perpendicular to the long α -helical chain axis. At 80 °C, their diffusion coefficients are close to each other. As reported previously, the determined $D_{\parallel}$ and $D_{\perp}$ values of *n*-alkane, *n*-C₂₄H₅₀, in the rotator phase like the liquid crystalline state, which takes the all-*trans* zigzag conformation, are 1.64×10^{-10} and $2.70 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$, respectively. The diffusion of the *n*-alkane in the rotator phase along the long chain axis is slower by roughly two times than that perpendicular to the long chain axis. This is opposite to the results of POLG. From the number of amino acid residues of POLG (ca. 780) considered here, the α -helical chain length is roughly estimated to be ca. 117 nm by using the pitch of an α -helix chain per one amino acid residue to be 0.15 nm. However, the chain length of *n*-C₂₄H₅₀ with the all-*trans* zigzag conformation is roughly estimated to be ca. 1.8 nm. From these simple estimations, it is seen that the corresponding rod-like POLG is much longer than *n*-C₂₄H₅₀. This leads to the experimental finding that the diffusion of the POLG along the long α -helical chain axis is much faster than that perpendicular to the long α -helical chain axis.

As for POLLG, only the isotropic diffusion coefficients were determined for an interval of 10 °C in the temperature range from 30 to 80 °C (Figure 14). The diffusion coefficients of POLLG in the liquid crystalline state were determined as a function of temperature similarly to POLG. It is shown that with an increase in temperature from 30 to 80 °C, the D value increases gradually from 4.9×10^{-11} to $1.4 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. Let us compare these D_{iso} values with those of POLG calculated from the determined $D_{\parallel}$ and $D_{\perp}$ values. As the temperature is increased from 60 to 80 °C, the D_{iso} values of POLG increase gradually from 3.53×10^{-11} to $1.02 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ and those of POLLG increase from 4.9×10^{-11} to $1.40 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. At 60 °C, POLLG in the thermotropic liquid crystalline state diffuses faster by ca. 2.8 times than POLG irrespective of the same α -helical chain length and at 80 °C their diffusion rates are close to each other. At 60 °C such a large difference in D_{iso} between POLG and POLLG may come from large differences in their side-chain conformation and molecular motion (as seen from the T_2 experiments below). The melting temperature of side chain crystallites in POLG is ca. 60 °C and that of POLLG is below -40 °C as DSC measurements as reported previously.³⁴ This means that at 60 °C the side chains of POLLG are undergoing much faster *trans-gauche* exchange around the C-C bond compared with those of POLG, and the expansion of the side chains from the main chain in the former is much smaller than that of the latter. At a higher temperature (80 °C) their mobilities are close to each other. This leads to the difference in D_{iso} between POLG and POLLG.

In order to understand the diffusion process of the polypeptide in the thermotropic liquid crystalline state more thoroughly, the activation energy $E^{\ddagger}$ for diffusion process can be determined. $E^{\ddagger}$ can be obtained from the plots of $\ln D$ against $1/T$ within the temperature range from 60 to 80 °C. As for POLG, the measured values of $E^{\ddagger}$ are 33.4, 77.4 and 49.8 kJ mol^{-1} for $D_{\parallel}$, $D_{\perp}$, and D_{iso} , respectively. However, the activation energy for D_{iso} of POLLG is determined to be 20.6 kJ mol^{-1} . From these experimental results, it can be said

that the activation energy for the diffusion process for POLLG in the thermotropic liquid crystalline state is much lower than that of POLG. In the case of POLG, the activation energy for the diffusion along the α -helical chain axis is much lower than that in the direction perpendicular to the α -helical chain axis.

1 INTRODUCTION

The suitability of NMR spectroscopy for monitoring exchange processes of molecules has been realized since the earliest days of the technique. In those formative years, rate processes were studied primarily by their effects on internal resonance frequencies of nuclei (bandshape analysis)¹ or on signal intensities (magnetization transfer experiments).^{2,3} The first method relies on exchange processes occurring at frequencies comparable to differences in nuclear resonance frequencies $\Delta\nu_i$ (see *Chemical Exchange Effects on Spectra*), whereas the second approach requires exchange rates to be comparable to spin–lattice relaxation rates R_{1i} . The consequences of such criteria are that bandshape analysis methods are applicable to rather faster rate processes, with pseudo-first-order rate constants k in the range $1\text{--}10^4\text{ s}^{-1}$, than magnetization transfer methods, where typically k values are in the range $10^{-2}\text{--}10^2\text{ s}^{-1}$. Such ranges, however, are very imprecise, and depend on the nucleus chosen to monitor the process and the nature of the chemical species itself—for example, whether it is diamagnetic or paramagnetic.

In magnetization transfer experiments, based on the classic work of Forsén and Hoffman,^{2,3} nuclei in one of the exchanging sites are labeled by disturbing their energy population distribution, either by selective decoupling, which equalizes their populations (saturation), or by applying a selective 180° pulse, which inverts their populations (inversion). Chemical exchange causes these nuclei to move to one or more different sites, thus introducing a further disturbance to the populations in that site. This leads to a time dependence of populations of exchanging sites, which is reflected in the changing intensities of signals following the perturbing pulse. Measurements of this intensity variation can provide accurate exchange rate data. The method can be made very reliable for two-site exchange,⁴ and has been very widely applied. The method can also be generalized for multisite exchange, where it has been shown that for a system of N exchanging sites $\frac{1}{2}N(N-1)$ exchange rates and N spin–lattice relaxation rates need to be evaluated.⁵ However, this requires many experiments, and this type of problem is far more efficiently handled by two-dimensional experiments^{6–8} (see *Multidimensional Spectroscopy: Concepts*), which is the subject of this article.

Rate processes that cause exchange of magnetization between nuclear sites are many and varied. They range from examples of intermolecular exchange (e.g., ligand or solvent exchange processes) to subtle intramolecular rearrangements between chemically identical species (e.g., fluxional processes) (see *Fluxional Motion*). This article presents the basic theory of two-dimensional exchange spectroscopy (EXSY), illustrates the scope and limitations of the technique, and provides examples of its application, employing a variety of different sensor nuclei, to different areas of chemistry.

The focus will be on chemical exchange arising from structural rearrangements of molecules, but the reader is reminded that essentially the same technique is used for studying motional processes as revealed by cross relaxation rather than chemical exchange effects. In this context, the technique is known as two-dimensional NOE spectroscopy, and has been widely exploited⁹ (see *NOESY*).

2 THEORY AND METHODOLOGY OF 2D EXCHANGE SPECTROSCOPY

The application of 2D NMR for chemical exchange studies was first described by Jeener, Meier, Bachmann, and Ernst.¹⁰ Its theoretical basis was elaborated by Macura and Ernst,¹¹ and has been the subject of a number of reviews.^{12–15}

2.1 Basic EXSY Experiment

The fundamental principle of the EXSY experiment is the frequency labeling of the spin–lattice (longitudinal) magnetization of various sites before exchange occurs, in order that, after exchange, the pathways of magnetization can be traced back to their origins.

The basic pulse sequence is shown in Figure 1. A two-spin system of spins A and B, mutually interacting purely through chemical exchange with no cross relaxation, will be considered. Equal concentrations of spins (i.e., $k_{AB} = k_{BA} = k$), equal spin–lattice relaxation rates ($R_1^A = R_1^B = R_1$), and equal transverse relaxation times ($T_2^A = T_2^B = T_2$) will be assumed. After the first 90°_x pulse, the magnetization vectors will evolve in the (x', y') plane in the usual manner of free induction decay

Figure 1 Basic EXSY pulse sequence, showing typical variations in the mixing coefficients for diagonal and cross peaks during the mixing time t_m

2 TWO-DIMENSIONAL METHODS OF MONITORING EXCHANGE

(FID) for a period t_1 (evolution time). The total magnetization M^+ is given by

$$M^+ = M_y(t) + iM_x(t) \quad (1)$$

If exchange is slow, the effect of lineshape may be neglected, and the two magnetization components are given by

$$M_A^+(t_1) = M_{A0} \exp(i\omega_A t_1 - t_1/T_2) \quad (2)$$

$$M_B^+(t_1) = M_{B0} \exp(i\omega_B t_1 - t_1/T_2) \quad (3)$$

where $\omega_{A,B}$ are the effective precession frequencies in the rotating frame. When a second 90°_x pulse, the mixing pulse, is applied, the magnetization vectors are tipped into the $-z$ direction, the real components of the transverse magnetization being converted into longitudinal magnetization:

$$M_{AZ}(t_m = 0) = -M_{A0} \cos \omega_A t_1 \exp(-t_1/T_2) \quad (4)$$

$$M_{BZ}(t_m = 0) = -M_{B0} \cos \omega_B t_1 \exp(-t_1/T_2) \quad (5)$$

The imaginary x components are unaffected by this pulse, and may be destroyed by a field gradient pulse during the mixing time t_m . The t_1 -modulated longitudinal components in equations (4) and (5) migrate from one site to another by chemical exchange, with a rate constant k , while the spin-lattice relaxation attenuates the memory of the initial labeling:

$$M_{AZ} = M_{AZ}(t_m = 0) \frac{1}{2} [1 + \exp(-2kt_m)] \exp(-t_m R_1) + M_{BZ}(t_m = 0) \frac{1}{2} [1 - \exp(-2kt_m)] \exp(-t_m R_1) \quad (6)$$

$$M_{BZ} = M_{AZ}(t_m = 0) \frac{1}{2} [1 - \exp(-2kt_m)] \exp(-t_m R_1) + M_{BZ}(t_m = 0) \frac{1}{2} [1 + \exp(-2kt_m)] \exp(-t_m R_1) \quad (7)$$

The final 90°_x pulse converts these longitudinal components into observable magnetization. Double Fourier transformation will produce signals at $(\omega_1, \omega_2) = (\omega_A, \omega_A)$ and (ω_B, ω_B) for nuclei that have not exchanged during the time t_m . Nuclei that have exchanged sites will produce signals at (ω_A, ω_B) and (ω_B, ω_A) . The amplitudes $I_{kl}(t_m)$ of the diagonal and off-diagonal signals depend on the equilibrium magnetizations M_{j0} and on mixing coefficients $a_{kl}(t_m)$, which correspond to the factors in equations (6) and (7):

$$a_{AA} = a_{BB} = \frac{1}{2} [1 + \exp(-2kt_m)] \exp(-t_m R_1) \quad (8)$$

$$a_{AB} = a_{BA} = \frac{1}{2} [1 - \exp(-2kt_m)] \exp(-t_m R_1) \quad (9)$$

In this simple two-site exchange system, the equilibrium magnetizations M_{A0} and M_{B0} are equal, and the exchange rate can be determined from the ratio of diagonal and off-diagonal (cross peak) intensities:

$$\frac{I_{AA}}{I_{AB}} = \frac{a_{AA}}{a_{AB}} = \frac{1 + \exp(-2kt_m)}{1 - \exp(-2kt_m)} \approx \frac{1 - kt_m}{kt_m} \quad (10)$$

This intensity ratio is a sensitive function of the mixing time t_m , and care must be taken in the length chosen in order to obtain optimum accuracy of the rate constant. The amplitudes of the diagonal signals decay in the biexponential manner

Figure 2 Hydrogen-1 EXSY spectrum of *N,N*-dimethylacetamide, showing the *N*-methyl exchange cross peaks. Experimental conditions: 128 equidistant t_1 values from 0 to 1016 ms, each FID represented by 256 samples, and a mixing time $t_m = 0.5$ s. Note that diagonal signals go from top left to bottom right

with increasing mixing time, whereas the off-diagonal signals first increase owing to exchange and then decrease because of spin-lattice relaxation (see Figure 1). The optimal value of t_m corresponds to the region on the graph where the intensity of the cross peak is almost linearly proportional to t_m and well before it reaches a level where its intensity is more dependent on T_1 than on t_m . It has been shown theoretically¹³ that an approximate expression for the optimal value of t_m for an equally populated two-site exchange system is

$$t_m(\text{opt}) \approx (R_1 + 2k)^{-1} \quad (11)$$

One of the first reported EXSY spectra is shown in Figure 2.¹⁰ It depicts the diagonal and cross-peak signals of the *N*-methyl hydrogens of *N,N*-dimethylacetamide, which exhibit exchange due to the slow rotation about the C–N bond in the molecule.

This theory can be extended to general N -site exchange when $N \geq 3$ using a matrix formulation. This has been described fully elsewhere,^{12–15} and here space permits only a summary. For nuclei in site j , the initial 90°_x pulse causes their magnetization to evolve according to

$$M_j = M_{j0} \exp(i\omega_j t_1 - t_1/T_{2j}) \quad (12)$$

The second 90°_x pulse, plus a gradient pulse, converts this transverse magnetization to z magnetization according to

$$M_{jz}(t_m = 0) = -M_{j0} \exp(i\omega_j t_1 - t_1/T_{2j}) \quad (13)$$

During the mixing period, chemical exchange and longitudinal relaxation affect this magnetization. We define m_j to be the deviation of M_{jz} from its equilibrium value by

$$m_j = M_{jz} - M_{j0} \quad (14)$$

The time dependences of these deviations are given by equations of the type

$$\frac{dm_1}{dt} = -\left(R_{11} + \sum_l k_{1l}\right)m_1 + k_{21}m_2 + \cdots + k_{N1}m_N \quad (15)$$

$$\frac{dm_2}{dt} = k_{12}m_1 - \left(R_{12} + \sum_l k_{2l}\right)m_2 + \cdots + k_{N2}m_N \quad (16)$$

$\vdots$

$$\frac{dm_N}{dt} = k_{1N}m_1 + k_{2N}m_2 + \cdots - \left(R_{1N} + \sum_l k_{Nl}\right)m_N \quad (17)$$

where k_{ij} are the rate constants for exchange from site i to site j , and R_{1i} are the spin-lattice relaxation rates of nuclei in site i . These equations may be written in matrix form as

$$\dot{\mathbf{m}} = -\mathbf{L}\mathbf{m} \quad (18)$$

where $\mathbf{m}$ is a column matrix whose components are $m_1, m_2, \dots, m_N$, $\dot{\mathbf{m}}$ is the time derivative of $\mathbf{m}$, and $\mathbf{L}$ is a square $N \times N$ matrix whose off-diagonal elements are $L_{ij} = -k_{ji}$ and whose diagonal elements are $L_{ii} = \sum_j k_{ij} + R_{1i}$. This matrix $\mathbf{L}$ contains all site-to-site rate constants, and the problem is to relate the elements of $\mathbf{L}$ to the signal intensities in an EXSY spectrum. The formal solution is given by

$$\mathbf{m}(t_m) = \exp(-\mathbf{L}t_m)\mathbf{m}(0) \quad (19)$$

where $\mathbf{m}(0)$ is the column matrix of the deviations $m_j(0)$ at the start of the mixing period.

The explicit expression for the intensity of any EXSY signal (diagonal or off-diagonal) at ω_i along the frequency coordinate ω_2 and at ω_j along ω_1 is given by¹³

$$I_{ij}(t_m) = M_{j0} \exp(-\mathbf{L}t_m)_{ij} \\ = \left(\delta_{ij} - t_m L_{ij} + \frac{1}{2} t_m^2 \sum_k L_{ik} L_{kj} - \dots \right) M_{j0} \quad (20)$$

where $\delta_{ij} = 1$ ($i = j$) or 0 ($i \neq j$). Equation (20) shows that an EXSY spectrum represents a graphical display of the exchange pathways, with cross peaks corresponding to nuclei that exchange sites. Intensities of signals correspond to the exponential of the matrix $\mathbf{L}$, allowance being made for the fact that the mathematical convention of a matrix is with the diagonal running from top left to bottom right whereas an EXSY spectral map consists of a diagonal running from bottom left to top right.

2.2 Extraction of Rate Data from EXSY Spectra

The complexity of equation (20) arises because cross peaks for exchange between sites i and j can arise from both direct exchange $i \rightleftharpoons j$ and indirect exchange, $i \rightleftharpoons k \rightleftharpoons j$. For very short t_m values, the indirect cross peaks vanish, and equation (20) simplifies. However, short t_m values cause all cross-peak intensities to be low, so this approach is of limited applicability. Three strategies have been employed to extract reliable rate data from EXSY spectra.

2.2.1 Initial Rate Approximation

This involves measuring cross-peak intensities as a function of small values of t_m .¹⁶ Rate constants k_{ij} are determined from the slope of the graph of $I_{ij}(t_m)$ versus $M_{j0}(t_m)$, but the method involves repeating the experiment for a range of mixing times and extrapolating to $t_m = 0$, which is a time-consuming approach.

2.2.2 Iterative Analysis

In this method,¹⁷ trial values of k_{ij} and R_{1i} are chosen, and a total magnetization transfer matrix $\mathbf{L}$ is constructed. Diagonalization of this yields a signal intensity matrix, which is compared with the experimental intensity array. An iterative fitting is then performed by varying exchange and relaxation rates until a 'best fit' is obtained.

2.2.3 Direct Matrix Transformation

Unlike the previous method, this approach does not require any prior knowledge of k_{ij} and R_{1i} values, and uses a matrix method for inverting equation (20) first presented by Perrin and Gipe.¹⁸ It is based on expressing an EXSY spectrum as an intensity matrix $\mathbf{I}$ with elements

$$I_{ij} = p_i \sum_{k=1}^N A_{ijk} \exp(\lambda_k t_m) \quad (21)$$

where p_i is the relative population of site i , and A_{ijk} and λ_k are constants depending on the experimental conditions. In matrix form,

$$\mathbf{I} = \mathbf{P}\mathbf{J} \quad (22)$$

where $\mathbf{P}$ is a column matrix of site populations and $\mathbf{J}$ is a matrix with elements $\exp(\lambda_k t_m)$. The kinetic matrix $\mathbf{K}$ consisting purely of rate constants k_{ij} can be related to the EXSY spectral intensity matrix $\mathbf{I}$ by

$$\mathbf{I} = \mathbf{P} \exp(\mathbf{K}t_m) \quad (23)$$

Now, $\mathbf{J} = \mathbf{I}\mathbf{P}^{-1}$, and diagonalization of $\mathbf{J}$ will generate the array $\exp(\mathbf{\Lambda}t_m)$:

$$\mathbf{J} = \mathbf{X} \exp(\mathbf{\Lambda}t_m) \mathbf{X}^{-1} \quad (24)$$

Taking the natural logarithm of the eigenvalues and dividing by t_m , i.e.,

$$\frac{\ln \mathbf{J}}{t_m} = \frac{\mathbf{X} \ln \exp(\mathbf{\Lambda}t_m) \mathbf{X}^{-1}}{t_m} \quad (25)$$

generates the matrix $\mathbf{\Lambda}$.

Finally, matrix multiplication

$$\mathbf{X}\mathbf{\Lambda}\mathbf{X}^{-1} = \mathbf{K} \quad (26)$$

yields the kinetic matrix $\mathbf{K}$, consisting of all rate constants for the multisite process. It should be noted that in this formulation,¹⁹ all off-diagonal elements are positive and diagonal elements negative, in contrast to the kinetic part of the $\mathbf{L}$ matrix defined earlier [equation (18)].

It is also necessary to include spin-lattice relaxation of nuclei. This can take the form of a relaxation matrix $\mathbf{R}$, which when added to $\mathbf{K}$ gives the total magnetization transfer matrix $\mathbf{L}$:

$$\mathbf{L} = \mathbf{K} + \mathbf{R} \quad (27)$$

The matrix $\mathbf{R}$ consists of diagonal elements $-R_{1i}$ and off-diagonal elements $-\sigma_{ij} = -R_{ji}$, where these refer to cross-relaxation rates.

In cases where cross relaxation between nuclei can be neglected, the above procedures have been incorporated into a general computer program.¹⁹ Its input consists of the number of exchanging sites (2–8), the relative populations of each site, spin-lattice relaxation rates, and experimental signal intensities, the latter being measured by integration of appropriate rows of the 2D spectral map, or, preferably, by volume integration. The accuracy of the final rate data depends on the choice of mixing time and on the accuracy of measured signal intensities. Pure absorption mode spectra

Figure 3 Partial phase-sensitive ^1H EXSY spectrum of ^{15}N -enriched acetamide obtained with the TPPI method for $t_m = 400$ ms. A 1 K data block and spectral width in ω_2 of 614 Hz were used. A total of 256 t_1 values was used and zero filled to 1 K, resulting in a digital resolution of $1.2 \text{ Hz point}^{-1}$ in both frequency domains

provide better resolution of closely separated signals than magnitude mode spectra. This can be achieved using time proportional phase incrementation (TPPI), and so this is the recommended procedure for accurate quantitative EXSY studies. The ^1H EXSY spectrum of ^{15}N acetamide using this procedure is shown in Figure 3.²⁰ Both NH signals are doublets [$^1J(\text{NH}) \approx 90 \text{ Hz}$], and exhibit cross peaks due to slow C–N bond rotation. Intensity measurements of all eight signals provided accurate rate and R_1 values for the NH hydrogens. The much weaker cross peaks are due to ^{15}N spin–lattice relaxation occurring during the mixing period.

The assessment of errors in EXSY-based rate constants is an important matter which has received careful consideration.^{19,21,22} The choice of mixing time has already been shown to be crucial. In multisite exchanges, it is usually impossible to find a single value of t_m that is optimal for all exchange pathways. Additional cross peaks due to indirect exchanges [equation (20)] may then arise if the mixing time is considerably greater than optimal, and so qualitative interpretations of exchange pathways from EXSY spectra must be made with caution.

2.3 Separation of Chemical Exchange and Cross-Relaxation Effects

The theoretical treatment above has neglected cross relaxation between nuclei; i.e., off-diagonal elements of the matrix $\mathbf{R}$ have been assumed to be negligibly small. This is generally valid for intermolecular exchanges and studies of intramolecular exchange using low-abundance sensor nuclei (e.g., ^{13}C). Also, it is often valid for studies of abundant nuclei (e.g., ^1H , ^{19}F , and ^{31}P) in small molecules, which can undergo rapid tumbling in solution. For large, slowly tumbling molecules, however, separation of chemical exchange and cross-relaxation rates is essential.

Cross-relaxation rates are given by

$$\sigma_{ij} = \frac{\gamma^4 \hbar^2 \tau_c}{10 r_{ij}^6} \left(\frac{6}{1 + 4\omega^2 \tau_c^2} - 1 \right) \quad (28)$$

where r_{ij} is the distance between nuclei i and j , and τ_c is the rotational correlation time of the molecule. The r^{-6} dependence provides proximity information, which has been widely exploited in conformational studies of complex molecules.⁹ For small molecules, where τ_c is short, cross-relaxation cross peaks are of opposite sign to diagonal signals, whereas for macromolecules with relatively large τ_c values, cross-relaxation signals are of the same sign as the diagonals. Pure absorption mode (TPPI) spectra, therefore, can in theory distinguish the two cases, but in either case cross-peak intensities may not reflect chemical exchange alone.

Separation of cross relaxation and chemical exchange is most easily achieved by temperature dependence studies, since k_{ij} values increase greatly with temperature whereas σ_{ij} values do not. More recently, new pulse sequences have been suggested for achieving this separation. These include zz-EXSY,²³ an interlayed NOESY/ROESY method,²⁴ and gradient-enhanced exchange spectroscopy (GEXSY).²⁵

2.4 One-Dimensional Variants of EXSY

The time required to obtain kinetic data from EXSY experiments can often be considerable, especially if long relaxation delays, long mixing times, and high digital resolution in both dimensions are required. Much time is incurred scanning through the whole range of incremental evolution periods, t_1 , yet the majority of rows in the final spectrum do not contain useful information. However, certain t_1 values cannot simply be omitted, since each value contributes to all frequencies through the FID. One method for shortening the experimental time would be to dispense with the t_1 period completely and rely on selective excitation (see *Selective Pulses*). The feasibility of this approach has been demonstrated for COSY experiments and is known as pseudo-COSY (ψ -COSY).²⁶ A similar technique has recently been proposed for exchange spectroscopy. It is described as multiplet-selective excitation or MUSEX,²⁷ and is based on selective excitation of only one nucleus of a coupled system using a typical DANTE pulse²⁸ (see *Double Resonance*).

Another variant uses the normal nonselective pulse sequence and difference spectroscopy.²⁹ For N -site exchange, data for N evolution times must be collected, measuring each at zero and nonzero mixing times. Difference spectra obtained by subtracting the equilibrium spectrum from spectra recorded both without and with mixing yields exchange information. For a system of three spins A, B, and C, six one-dimensional spectra are measured for three t_1 periods, each without and with mixing. It follows that

$$\begin{bmatrix} A(t_m) - A_0 \\ B(t_m) - B_0 \\ C(t_m) - C_0 \end{bmatrix} = \exp(-\mathbf{L}t_m) \begin{bmatrix} A(t_m = 0) - A_0 \\ B(t_m = 0) - B_0 \\ C(t_m = 0) - C_0 \end{bmatrix} \quad (29)$$

The matrix $\mathbf{L}$ can then be computed by a version of the back transformation method (Section 2.2.3). Greater accuracy can be achieved if the experiment is performed for more t_1 values than are strictly necessary.³⁰

2.5 Other Variants of EXSY

In 1989, Jeener, one of the pioneers of 2D NMR and its application to chemical kinetics, returned to this subject by examining the theoretical basis of the bandshapes of EXSY signals.³¹ He has shown that the shapes, particularly of off-diagonal signals, provide a clear signature of the chemical exchange process even for a single temperature. Superoperator theory was applied to one- and two-spin exchanging signals. Computation, however, is not trivial, and no obvious advantages of this approach over conventional 1D bandshape analysis or 2D EXSY experiments are apparent at this stage.

In its most general form, the EXSY or NOESY pulse sequence involves three time variables, t_1 , t_m , and t_2 , Fourier transformation of all of which would lead to three-dimensional spectra. In practice, however, the mixing time t_m is not taken as a time variable, and 2D spectra based on a very limited range of t_m values are usually obtained. An alternative approach is to make t_m proportional to t_1 (i.e., $t_m = \kappa t_1$). The resulting 'accordion' technique³² leads to EXSY-type spectra in which the signals are distorted from their usual shapes, and rate constants need to be extracted from signal widths rather than intensities. This restricts the versatility of the method.

Three-dimensional NMR experiments are now rapidly gaining ground³³ (see *Multidimensional Spectroscopy: Concepts*). In 3D exchange spectroscopy, two successive exchange processes may be mapped. These may be chemical exchange (EXSY) or cross relaxation in either the laboratory frame (NOESY) or in the rotating frame (ROESY), resulting in such experiments as EXSY-EXSY and NOESY-ROESY. In the context of this article, it should be mentioned that a 3D EXSY-EXSY spectrum of heptamethylbenzenonium sulfate (in sulfuric acid) has been obtained,³³ showing the 1,2-commutation of the methyl group round the ring. It is too early to predict whether such experiments will provide more insight into dynamic processes than can be achieved by 1D and 2D experiments. Dynamic studies of highly complex molecules would appear to be most likely to gain by the extra frequency dimension.

3 APPLICATIONS OF EXSY

A few representative examples of EXSY experiments using different sensor nuclei will now be given.

3.1 Carbon-13 and Hydrogen-1

In Section 2.3, the separation of chemical exchange and cross-relaxation contributions to cross peak intensities was discussed. This problem does not arise in EXSY spectra of low-abundance nuclei (e.g., ^{13}C), where cross-relaxation effects are negligible, but is a potential problem with abundant nuclei such as ^1H . A specific case has been described where the effects of ^1H - ^1H cross relaxation have been quantified.³⁴ In the trinuclear rhenium complex $[\text{Re}_3(\mu\text{-H})_4(\text{CO})_{10}]$, carbonyl scrambling occurs by a concerted mechanism (see *NO315-Organometallic Compounds*), the kinetics of which can be measured accurately by ^{13}C EXSY. Lower accuracy would be attached to ^1H -EXSY-based rates, since one-dimensional

selective perturbation data showed that the cross-relaxation rate of a pair of bridging hydrogens was 0.04 s^{-1} , a small but not negligible rate. On the other hand, a combined ^{13}C and ^1H EXSY study of the metal migration in the cyclooctatetraene (COT) complexes $[\text{M}(\text{CO})_3(\eta^6\text{-COT})]$ ($\text{M} = \text{Cr}$ or W) produced kinetic data in excellent agreement with each other, indicating that ^1H - ^1H cross relaxation in this case was negligible.³⁵

3.2 Lithium-7

The first ^7Li EXSY spectra have recently been produced in connection with a kinetic study of the complex [lithium monobenzo-15-crown-5] $^+$ in nitromethane.³⁶ Mixing times varied between 5 and 100 ms, nine experiments being performed, each requiring 1 h of spectrometer time. Rate data were in close agreement with those measured by bandshape analysis, showing that the EXSY method can be applied with confidence to systems such as cryptands, where exchange is too slow for bandshape treatment.

3.3 Boron-11

The well-known redistribution reactions of boron trihalide mixtures have been examined by ^{11}B EXSY.³⁷ The particular mixture studied was a nearly 1:1 M mixture of BCl_3 and BBr_3 at 400 K. The spectrum for a mixing time of 50 ms is shown in Figure 4. Rate data were calculated by the three methods described in Section 2.2, with the direct matrix diagonalization method being preferred.

Figure 4 Boron-11 EXSY spectrum of a 1.05:1.0 M mixture of BCl_3 and BBr_3 at 400 K. The mixing time was 50 ms. The F_1 dimension contained 128 points, zero filled to 256 points. The F_2 dimension contained 512 real plus complex points. The number of scans per FID was 96

3.4 Silicon-29

Much insight into the silicate anion exchange pathways in ^{29}Si -enriched potassium silicate solutions has been gained by ^{29}Si EXSY.³⁸ Four intermolecular exchanges were discovered, involving monomeric anion, dimer, linear trimer, linear tetramer, and substituted cyclic trimer species, plus two intramolecular exchanges. Although this was only a qualitative study, it demonstrates the power of 2D EXSY over its 1D counterpart.

3.5 Phosphorus-31

This nucleus is well suited to EXSY studies in view of its high receptivity, wide chemical shift range, and common absence of ^{31}P – ^{31}P cross relaxation. Numerous studies have been reported, one example being the octahedral organochromium(0) complexes $[\text{Cr}(\text{CO})_2(\text{CX})\{(\text{MeO})_3\text{P}\}_3]$ ($\text{X} = \text{S}, \text{Se}$).³⁹ These stereochemically nonrigid complexes undergo rearrangements via trigonal-prismatic (Bailar) intermediates. The ^{31}P EXSY experiments were of the ‘accordion’ type³² (Section 2.5), with the factor κ having a magnitude of 30.

3.6 Vanadium-51

Quantitative kinetic data on oligomerization reactions of vanadate in aqueous solutions has been provided by ^{51}V EXSY.⁴⁰ At pH 8.6, the EXSY spectrum shows all major oligomers, namely monomer, dimer, tetramer, and pentamer, exchanging with each other. Rates of several exchange pathways were identified. Mixing times were chosen in the range 8–10 ms.

3.7 Tin-119

The first example of ^{119}Sn EXSY was in connection with the dynamic stereochemistry of a ditin compound $\text{CH}_2[\text{PhSn}(\text{SCH}_2\text{CH}_2)_2\text{NMe}]_2$.⁴¹ The spectrum, with a short mixing time of 5 ms, showed pairwise exchange of three isomers associated with uncorrelated isomerization of each tin centre. The same research group has also investigated $[\text{MeSn}(\text{CH}_2\text{CH}_2\text{CH}_2)_2\text{NMe}]_2$, which in solution exists as at least three isomers, two of which interconvert at rates measurable by ^{119}Sn EXSY.⁴²

3.8 Tellurium-125

Platinum(IV) complexes of the type $[\text{PtXMe}_3\{\text{MeE}(\text{CH}_2)_n\text{EMe}\}]$ ($\text{E} = \text{S}, \text{Se}, \text{Te}$; $\text{X} = \text{Cl}, \text{Br}, \text{I}$; $n = 2, 3$) undergo a variety of internal rearrangements, the most facile being pyramidal inversion of the coordinated chalcogen atoms. When the chalcogen, E, is Se or Te, the inversion process can in theory be followed by ^1H , ^{13}C , ^{77}Se , ^{125}Te , and ^{195}Pt spectra. To avoid any complications from cross-relaxation effects, the rare nuclei are the preferred probes. The inversion process causes exchange between four isomers according to Scheme 1.

For the complex $[\text{PtIme}_3\{\text{MeTe}(\text{CH}_2)_3\text{TeMe}\}]$, the Te inversion rates were measured by ^{125}Te EXSY.⁴³ Cross peaks were detected between the DL and *meso* signals only, indicating that rates of synchronous inversion of both Te atoms are negligible.

Scheme 1

3.9 Platinum-195

^{195}Pt EXSY experiments are particularly powerful in monitoring exchange rates in the above Pt(IV) complexes. The EXSY spectrum of $[\text{PtIme}_3(\text{MeSCH}_2\text{CH}_2\text{SMe})]$ is illustrated in Figure 5. The three isomers are identified as shown, the signals due to DL and *meso*(1) also possessing ^{13}C satellites. For the chosen mixing time of 0.3 s, cross peaks were detected between all three species. The inversion process is strictly represented by a four-site exchange problem (Scheme 1), but, when monitored by ^{195}Pt nuclei, it reduces to a three-site exchange since the DL pair are indistinguishable. Signal

Figure 5 Platinum-195 EXSY spectrum of $[\text{PtIme}_3(\text{MeSCH}_2\text{CH}_2\text{SMe})]$ at 253 K. The mixing time was 300 ms. The F_1 dimension contained 256 points, zero filled to 512 points. The F_2 dimension contained 1024 points

intensity data from the spectra were used to set up the intensity matrix **I** as defined earlier,¹⁹ and the relative populations of the isomers enabled the matrix **P** to be constructed. The matrix conversion program¹⁹ then generated the kinetic-plus-relaxation matrix **L**, the off-diagonal elements of which provided rate constant magnitudes, namely, $k_{12} = 0.52 \pm 0.03 \text{ s}^{-1}$, $k_{23} = 0.50 \pm 0.03 \text{ s}^{-1}$, and $k_{13} = 0.004 \pm 0.04 \text{ s}^{-1}$. This latter rate constant for synchronous double inversion of both sulfur atoms is clearly zero within experimental uncertainty, despite the appearance of weak cross peaks I_{13} and I_{31} . This illustrates the point made earlier (Section 2.2) that the existence of a cross peak does not necessarily imply direct exchange between the two sites in question, and so qualitative interpretations of EXSY spectra must be made with considerable caution. The same research group has studied the sulfur inversion dynamics of $[\text{PtMe}_3(\text{MeSCH}_2\text{CH}_2\text{SEt})]$.⁴⁴ This constitutes a four-site exchange problem, a case too complex to be analyzed by total bandshape analysis. In contrast, the ^{195}Pt EXSY spectrum provided definitive rate data for the six distinct inversion pathways.

1 INTRODUCTION

A simple electrolyte solution consists of at least three different constituents, namely the solvent molecules, cations and anions. Many systems, e.g. those of biological, geological or industrial interest, consist of mixed solvents and/or mixed electrolytes and have correspondingly higher numbers of constituents. Hence, electrolyte solutions are typical multicomponent systems and therefore not easily accessible to many investigational methods, including a number of spectroscopic techniques, where signal contributions from different constituents can overlap. However, NMR spectroscopy represents an exception among the spectroscopic techniques since it offers important advantages with respect to liquid multicomponent solutions, and electrolyte solutions are particularly well suited to investigation by NMR techniques.

The main advantages of NMR are: (i) the generally narrow resonance lines in liquid electrolytes, enabling the detection of small chemical shift differences or small line broadening effects; and (ii) the selectivity of NMR allows an overlap-free observation of distinct constituents, even in a complex mixture. This selectivity, the most important advantage, comes from normally well resolved NMR lines due to the chemical shift differences, e.g. in ^1H or ^{13}C spectra of electrolyte solutions of simple ions, allowing the distinction of solvent molecules and ionic species by NMR of the same nuclide. Even more important for the selectivity of NMR is the huge number of different nuclides from the whole Periodic Table which can be utilized, in particular when ionic species or their nearest neighborhood can be observed. A third advantage of NMR, especially for equilibrium studies, arises from the fact that the NMR experiment at the extremely low energies in the rf region does not disturb the thermal equilibrium of the system under observation.

The aim of NMR studies of electrolyte solutions is to gain information about the structure and dynamics of liquid systems on a microscopic level. Thus, in contrast to the well-known applications of NMR to the study of molecular structures, we are dealing here with structural and dynamical effects, which are caused by intermolecular interactions. These intermolecular interactions are often relatively weak and compared with chemical bonds less sensitive to distance and orientation, and therefore the 'structure' of a liquid solution is less sharply defined.¹ The best way to describe the structure of liquids and solutions is the use of pair correlation functions (or radial distribution functions) $g_{ij}(r)$, which are defined by

statistical mechanics and which represent a measure of the probability of finding a molecule (or atom) i at a distance r from molecule (or atom) j . Unfortunately, NMR techniques do not yield $g_{ij}(r)$ directly, but certain nuclear magnetic relaxation rates $1/T_1$ are related to an integral over a pair correlation function. We will see that in NMR studies of electrolytes changes in the dynamics of the solvent molecules and of the ionic species are also often interpreted as a consequence of structural changes, and therefore sometimes a mixture of a structural and a dynamical description is used.²

The observation and detection of intermolecular interactions requires the measurement of quantities which are sensitive to intermolecular processes. This is the reason why in NMR studies on electrolyte solutions the measurement of nuclear magnetic relaxation times T_1 and T_2 (**Relaxation: An Introduction**) predominates by far over the measurement of chemical shifts and J couplings, the latter playing an almost negligible role.

The most characteristic property of electrolyte solutions is the electrical conductivity, that is the charge transport by migration of ionic species in an electric field. Therefore it is clear that an understanding of the translational motions in electrolytes is of outstanding importance. Here also NMR offers appropriate and unique measuring techniques for the study of translational displacements of selected species, namely the pulsed magnetic field gradient (PFG) spin echo techniques. These allow the selective measurement of translational diffusion coefficients (see **Diffusion and Flow in Fluids** and **Diffusion Measurements by Magnetic Field Gradient Methods**) of solvent molecules as well as of many ionic species, and also allow mobility measurements³ of charged particles (see **Electrophoretic NMR**).

Taking all these special advantages of NMR into consideration, it is not surprising that in the very early years of NMR, after the introduction of the Bloembergen, Purcell and Pound theory⁴ for T_1 relaxation in liquids, NMR studies on electrolyte solutions were already being performed, and since then an enormous amount of work has been published. Without any doubt, during the last 40 years NMR has developed into the most successful tool for investigating the microscopic properties of electrolyte solutions. Consequently, during the last 30 years a large number of reviews and book articles have appeared where the reader can find detailed descriptions of methods and applications.

The first really comprehensive review of the field of interest was given by Deverell in 1969.⁵ This article was followed in 1986 by a second extensive review by the present author in the same review series.⁶ A further comprehensive article, which gives a good introduction to the theoretical background of the different NMR methods used in the study of electrolyte solutions has been given by Hertz.⁷ Most of the other accounts are devoted to selected methods and fields of application, and the most important of these will be used as references in the corresponding sections of the present contribution. The scope of the present article is confined to simple electrolyte solutions, excluding solutions of ionized macromolecules as polyelectrolytes or of complex organic ions. Thus the main emphasis lies on diamagnetic solutions of small (mostly inorganic) ions. More information on paramagnetic solutions may be found in another article in this Encyclopedia (see **Paramagnetic Relaxation in Solution**).

2 STRUCTURAL STUDIES OF SIMPLE ELECTROLYTE SOLUTIONS

In this section it will be shown what information can be obtained from NMR techniques when ‘microstructural’ details of an electrolyte solution are required. It has already been mentioned that pair correlation functions $g_{ij}(r)$ cannot be derived directly from NMR measurement; however, in certain cases we can obtain a relatively well defined integral of $g_{ij}(r)$ over the first coordination sphere, delivering ‘coordination numbers’ n_c . We can also observe changes in this integral, which can reflect changes in $g_{ij}(r)$, when ion concentrations or generally the composition of the electrolyte solution are altered. We can further derive ‘closest distances of approach’, e.g. between ions and solvent molecules, and information can be gained about the orientation of solvent molecules near an ion. For example, the tendency to ion pair formation or to clustering of ions can be detected by NMR, equilibria studies are possible, and even the structural details of the ion pair configurations can be elucidated. All the microstructural properties of an electrolyte solution mentioned reflect the different interactions of relevance in such an electrolyte, namely the ion–solvent, the ion–ion, and the solvent–solvent interactions. Therefore this section is subdivided according to these interactions, and in the following discussion the most important NMR methods used under each topic are sketched and examples of typical applications are mentioned. Due to the unique importance of water on Earth, a great part of the NMR work on electrolytes has been devoted to the understanding of aqueous solutions. Furthermore, it is typical that for the investigation of a given electrolyte system the NMR of several nuclides, residing in solvent and solute species, is often utilized.

2.1 Solvation of Ions: Ion–Solvent Interactions

There are essentially four NMR measuring quantities which are used for structural solvation studies: the chemical shifts of the solute and solvent nuclei (e.g. ^1H and ^{17}O), the intermolecular dipole–dipole (DD) relaxation rate $(1/T_1)_{\text{inter}}^{\text{DD}}$ (e.g. of ^1H and ^{19}F), and the intermolecular quadrupole (QF) relaxation rate of nuclei (with $I > \frac{1}{2}$) residing in monatomic ions (e.g. ^{23}Na , ^{27}Al , ^{35}Cl , ^{39}K , ^{81}Br , ^{87}Rb , and ^{133}Cs) (see *Aluminum-27 NMR of Solutions, Quadrupolar Nuclei in Liquid Samples, Quadrupolar Transition Metal and Lanthanide Nuclei* and *Sodium-23 NMR*).

2.1.1 Determination of Coordination Numbers

The introduction of ions into a solvent gives rise to changes of the chemical shift in the solvent molecules which are closest to the ion. The chemical shift difference between the bulk solvent and molecules in the solvation sphere Δ_m might be of the order of 10–1000 Hz. (Δ_m is especially large for paramagnetic ions.) In liquid electrolytes the solvent molecules exchange between the bulk liquid and the ionic solvation sphere, and the residence time (or lifetime) τ_m in the solvation sphere can vary strongly since it is dependent upon the strength of the ion–solvent interaction. If $\tau_m \gg 1/\Delta_m$ (strong interaction and slow exchange) is valid, we have the very favorable case that the solvent NMR signals (e.g. of ^1H or ^{17}O)

Figure 1 80 MHz ^1H NMR spectrum of an aqueous solution of 2.1 M $\text{Al}(\text{ClO}_4)_3$ $T = -46^\circ\text{C}$. Left resonance line: water in the Al^{3+} hydration shell. Right resonance line: bulk water. The peak area integration (upper line) allows the exact determination of the coordination number using equation 1 ($n_c = 6$ is found)

from the bulk and solvation sphere can be observed separately, as shown in Figure 1. For example, this is the case for Be^{2+} , Mg^{2+} , Co^{2+} , Al^{3+} , Ga^{3+} , Ru^{2+} , Rh^{3+} , and Cr^{3+} (see also Figure 7). In this case the determination of the solvation numbers (primary coordination numbers) n_c of these cations by peak area integration is straightforward:

$$n_c = \frac{c_{\text{solv}}^*}{c_{\text{ion}}^*} \frac{I_B}{I_A + I_B} \quad (1)$$

where c_{ion}^* and c_{solv}^* are the ion and solvent concentrations on the molality scale, and I_A and I_B are the integrals of the signals of the free and bound solvent molecules, respectively.

It can be stated that the method described, which is due to Henry Taube (in 1960), is the most reliable source of information about the number of solvent molecules in the first solvation shell in liquid solutions. Results for n_c in aqueous solution are given in Hunt and Friedman⁸ and are indicated in Figure 7; the coordination numbers of nonaqueous solvents are given by Lincoln.⁹

However, many ions which are of interest in biological or chemical processes, for example the alkali and halide ions, interact relatively weakly with the solvent and therefore there is fast solvent exchange ($\tau_m \ll 1/\Delta_m$) and only one common resonance line is observed. The position of this averaged line of course depends on the coordination numbers of the ions (cations and anions), and several attempts have been undertaken to derive ^1H chemical shifts for individual ions in a given solvent,^{5,10,11} since these are required for the determination of coordination numbers. One can state that, in general, the results for n_c obtained in the fast exchange limit are less reliable than those for the slow exchange case.^{6,7}

2.1.2 The Intermolecular Dipole–Dipole Relaxation

The intermolecular DD relaxation (**Relaxation: An Introduction**) is an extremely helpful tool for structural research in liquid systems. The dipolar interaction between nuclei with large γ values (e.g. ^1H and ^{19}F) is so strong that it can be detected even over intermolecular distances. The magnetic field produced fluctuates due to the relative translational motion of the particles which carry the interacting spins, and it induces transitions between spin states and thus relaxation occurs.^{6,7} (It should be emphasized that essentially the same

is valid for intermolecular electron–nucleus DD interaction, see *Paramagnetic Relaxation in Solution*.)

Generally a relaxation rate $1/T_1$ can be written as:

$$\frac{1}{T_1} = C \cdot \frac{E_i^2}{h^2} \cdot f(\tau_c) \quad (2)$$

where C is a constant, h is the Planck constant, E_i is the interaction energy of the underlying relaxation process, and $f(\tau_c)$ is a function of the correlation time τ_c . When $\omega_0\tau_c \ll 1$ is valid, $f(\tau_c)$ can be replaced by τ_c and we can recognize from equation (2) that the relaxation rate is essentially a product of a quantity which is determined by structural properties (E_i^2) and a quantity which is controlled by the dynamics of the system (τ_c). Therefore relaxation rates can deliver information on both structure and dynamics. In a first approximation the correlation time for intermolecular processes τ_c^{trans} is proportional to $1/\bar{D} = 1/[2(D_1 + D_2)]$, where D_1 and D_2 are the translational diffusion coefficients of particles 1 and 2 carrying the DD interacting spins. Thus, if we measure $\bar{D}$ separately (e.g. by spin echo techniques) we obtain the structural information from $(\frac{1}{T_1})_{\text{inter}}$. One can write:^{6,12}

$$\left(\frac{1}{T_1}\right)_{\text{inter}}^{\text{DD}} = A_{ij} \cdot \frac{c}{\bar{D}} \quad (3a)$$

with:

$$A_{ij} = \frac{k}{a^4} \int_a^\infty \left(\frac{a}{r}\right)^6 g_{ij}(r) r^2 dr \quad (3b)$$

where k is a constant, a is the closest distance of approach between the interacting spins, and c is the concentration of the interacting spins in (spins cm^{-3}). A_{ij} is called the ‘ A parameter’ (association parameter) which contains information about the distances between two species in the solution. It should be pointed out that here intermolecular distances are probed by a microscopic magnetic field, which has the advantage that it is not disturbed in diamagnetic matter.

2.1.3 Aqueous Solutions

Other NMR techniques for the study of the solvation sphere are now described, in close connection with their application to special systems, and we begin with aqueous solutions.

Solvent isotope effects on reactions are of interest, e.g. for an understanding of acid and base catalyzed reactions. Therefore it is important to measure the deuterium/protium ratio in the solvation sphere of an ion, given by the so-called ‘fractionation factor’ ϕ_i . This factor can easily be determined by accurate water proton chemical shift measurements as a function of the variable $\text{H}_2\text{O}/\text{D}_2\text{O}$ ratio of the solvent water.⁶

In favorable cases the orientation of solvent molecules in the first coordination sphere of an ion can be determined from $(\frac{1}{T_1})_{\text{inter}}^{\text{DD}}$. In order to determine an ion–molecule configuration, one needs information about more than one ion–atom pair distribution function.⁷ However, isotopic substitution, e.g. replacing the nuclide ^{16}O by ^{17}O , or ^1H by ^2H , allows us to ‘switch on and off’ intermolecular DD interactions, and yields DD relaxation rates between the ionic nucleus and nuclei at different positions of the solvent molecule.^{6,7} In this way, for

example, the water orientation at the F^- and Li^+ ions has been investigated⁶ (see also Figure 2).

Figure 2 Ion–solvent configurations in the first solvation sphere as determined by intermolecular DD relaxation. The broad arrows indicate the relaxed spin under observation. The other arrows represent the DD interaction partners. (a) Hydration of F^- ; (b–d) Na^+ and I^- solvation by (b) formamide, (c) N -methylformamide, and (d) N,N -dimethylformamide. (Reproduced by permission of Elsevier Science Publishers from H. G. Hertz, in ‘The Chemical Physics of Solvation, Part B Spectroscopy of Solvation’, ed. R. R. Dogonadze, E. Kálmán, A. A. Kornyshev, and J. Ulstrup, Amsterdam, 1986, Chap. 7)

Intermolecular quadrupole relaxation of nuclides in monatomic ions, as mentioned at the beginning of this section, can also reveal certain structural details of the solvation sphere. This relaxation mechanism is caused by the interaction of the nuclear electric quadrupole moment with fluctuating electric field gradients⁶ (see *Quadrupolar Nuclei in Liquid Samples* and *Quadrupolar Transition Metal and Lanthanide Nuclei*). According to the Hertz theory,^{6,13} in electrolyte solutions the acting electric field gradient tensor arises from the electric fields of all electric mono- or multipoles in the closest neighborhood of the ion. In very dilute solutions

they arise solely from electric solvent dipoles in the first coordination sphere. Therefore, if the arrangement of solvent dipoles around an ion, for example Mg^{2+} in water, is of say, cubic symmetry the resulting electric field gradient at the center of the ion is quenched and we have comparatively long relaxation times T_1 and narrow resonance lines of the quadrupolar nucleus. Therefore, from linewidths and/or T_1 measurements of ionic nuclei we can learn something about the symmetry of the solvation shell. In water it turns out that Mg^{2+} has an extremely highly symmetric shell, and the field gradient is quenched by 99% of its maximum possible value, whereas for Na^+ the symmetry quenching is only about 50%,⁶ indicating a symmetry distortion in this latter case.

2.1.4 Non-Aqueous Solutions and Ions in Mixed Solvents

Under certain assumptions with respect to the shape of the pair correlation function⁷ it is possible to derive quite reliable values of a , the closest distance of approach [equation (3)] between the center of an anion and a distinct hydrogen atom of the solvent molecule in the electrolyte solution. These a values for a number of ions and solvents such as methanol, formamide, *N*-methylformamide (NMF) and formic acid are listed in the literature.⁷ Information from QF relaxation of ionic nuclei about the symmetry of solvation shells for various solvents and ions has also been obtained and can be found in the original literature.¹⁴ The orientation of highest probability of nonaqueous solvents in the first coordination sphere of ions has been investigated in the same manner as described above for water^{2,7} and results are shown in Figure 2 for the Na^+ and I^- ions in three amides.

Specific interactions or comparatively strong unspecific interactions between a given ion and a solvent can often be easily detected by using binary mixed solvents. If the local mole fraction $x_{\text{local},1}$ of a solvent 1 in the solvation sphere of an ion is higher than x_1 its macroscopic mole fraction in the mixture, solvent 1 has a stronger interaction with the ion than does solvent 2, and there is preferential solvation of the ion by component 1. NMR chemical shift or relaxation measurements of ionic nuclei (or sometimes of solvent nuclei) can provide a very valuable insight into the actual composition of the solvation shell and thus into preferential solvation or selective solvation (the latter corresponds to the special case $x_{\text{local},1} = 1$, $x_{\text{local},2} = 0$). A huge number of preferential solvation studies exist,^{6,15,16} allowing the determination of $\Delta G_{\text{ps}}^\ddagger$, the free energy of preferential solvation.¹⁵ Figure 3 shows the results of such a study, where $x_{\text{local},1}$ and $x_{\text{local},2}$ could be determined separately. Since $x_{\text{local},1} + x_{\text{local},2} = 1$ must be valid, the reliability of the result can easily be checked.¹⁷

An interesting phenomenon, which has been detected for the first time by different NMR methods, occurs in aqueous electrolyte solutions containing nonpolar (hydrophobic) solutes. This is the attraction of anions to the nonpolar groups, which are hydrophobically hydrated,^{13,18} a phenomenon which might be of general importance in various fields of pure and applied chemistry and life sciences.

2.2 Ion–Ion Interaction Effects

An extremely important aspect in the understanding of electrolyte solutions is the detection and elucidation of

Figure 3 Preferential solvation study of Na^+ in *N,N*-dimethylformamide (DMF)–methanol by $^{23}\text{Na}^+$ QF relaxation;¹⁷ x_{local} , the mole fraction of methanol ($\blacktriangledown$) and DMF ($\square$) in the first solvation sphere of Na^+ , is given as a function of x_{DMF} , the macroscopic mole fraction of DMF in the mixed solvent system. (---) Nonpreferential solvation. $T = 25^\circ\text{C}$

ion–ion interactions. For this problem the chemical shifts and relaxation data of nuclei residing in ions are utilized almost exclusively, and many examples from the NMR of metal nuclides are given by Dechter.¹⁶ In particular, in nonaqueous solvents there is often a strong tendency to ion pair formation or to complexation. If there are long-living complexes, different cation–anion–solvent complexes can be identified by their separate resonance lines, in, for example, metal nuclide NMR. A very informative example of such a case is given in Figure 4.

In dilute solutions of strong electrolytes the behavior of the Debye–Hückel ion–ion pair distribution function is clearly reflected in a $\sqrt{c}$ dependence of the relaxation rate $1/T_1$ of monatomic ionic nuclei such as $^7\text{Li}^+$, $^{23}\text{Na}^+$, $^{87}\text{Rb}^+$, and $^{35}\text{Cl}^-$ ⁶ (Figure 5). From intermolecular QF relaxation of ionic nuclei¹⁹ and intermolecular DD relaxation of ^1H or ^{19}F ,²⁰ the sharpening of the cation–anion pair correlation function with decreasing ionic strength can be observed by the determination of the quantity $(1/T_1)_{\text{inter}} \cdot (\bar{D}/c)$ [see equation 3, 43] as a function of concentration c .

The DD interaction of the electron spin on the paramagnetic Ni^{2+} ion with nuclei of other ions, such as Li^+ or Al^{3+} , is an excellent tool for probing the effective forces between ions in solution by comparing the NMR relaxation results with model potentials.²¹ The $^7\text{Li}^+$ and $^{27}\text{Al}^{3+}$ relaxation data revealed a surprisingly close distance of approach between Ni^{2+} and these cations in aqueous solution.⁶ Cation–anion mean force potentials have recently been very carefully investigated by ^1H and ^{31}P relaxation of $(\text{CH}_3)_4\text{P}^+$ in the presence of a paramagnetic anion by Fries and co-workers.²² These authors applied a refined theory of intermolecular DD relaxation.^{6,22}

Electric field gradients acting at quadrupolar ionic nuclei can also arise from neighboring ions, giving the so-called ‘ion–ion contribution’ to the QF relaxation of nuclei in monatomic ions.⁶ Despite the fact that this intermolecular (or interatomic) relaxation is of a complicated nature, attempts have been

Figure 4 78.2 MHz ^{27}Al NMR studies of AlCl_3 in acetonitrile (AN) at different salt concentrations. Seven different hexacoordinated complexes were detected: (1) $\text{Al}(\text{AN})_6^{3+}$; (2) $[\text{AlCl}(\text{AN})_5]^{2+}$; (3) *cis*- $[\text{AlCl}_2(\text{AN})_4]^+$; (4) *trans*- $[\text{AlCl}_2(\text{AN})_4]^+$; (5) *cis*- $\text{AlCl}_3(\text{AN})_3$; (6) *trans*- $\text{AlCl}_3(\text{AN})_3$; (7) *cis/trans*- $[\text{AlCl}_4(\text{AN})_2]^-$. (Reproduced by permission of Academic Press from F. W. Wehrli and S. Wehrli, *J. Magn. Reson.*, 1981, **44**, 197)

undertaken to derive from ion–ion relaxation rates models of clusters consisting of up to four ions.⁶

Studies of chemical equilibria for ion pair formation, for acid–base reactions or complexation reactions is an important practical field of NMR applications to electrolyte solutions, as shown in a recent review.²³ In these studies NMR parameters such as peak areas, chemical shifts and relaxation times are, in principle, used for the contactless and disturbance-free measurement of equilibrium concentrations which are needed for the determination of equilibrium constants. It should be emphasized once again that these NMR experiments can be performed under thermal equilibrium conditions.

2.3 Solvent–Solvent Interaction Effects in Electrolyte Solutions

The addition of salts to a pure or mixed solvent can alter the solvent–solvent interaction or the interaction of a

Figure 5 $^{35}\text{Cl}^-$ relaxation rates in aqueous solutions as a function of salt concentration c for different salts ($T = 25^\circ\text{C}$). At low concentrations the $\sqrt{c}$ dependence of $1/T_1$ can be clearly observed. (M. Holz and Xi-An Mao, unpublished data)

nonelectrolyte cosolute in the electrolyte solution. These often subtle effects can be investigated by ‘A parameter’ [equation (3)] studies where an increase of A_{ij} , e.g. as a function of salt concentration, indicates a sharpening of the solvent–solvent pair distribution function. Such a behavior has been found in water, when ‘structure-breaking’ salts such as RbBr and RbI are added.⁶ Another interesting example is the association behavior of nonpolar solutes or solutes with nonpolar groups in water when salts are added and where hydrophobic association can occur as an early stage of a salting-out effect. In a recent NMR study,²⁴ A_{22} for small hydrophobic solutes was determined with and without the presence of salts in water. It was shown that the salt influence follows the well-known empirical ‘Hofmeister’ (or ‘lyotropic’) series for the salting out of biomolecules, thus opening up the possibility of model studies by this NMR technique.

3 DYNAMICS IN ELECTROLYTE SOLUTIONS

Structural peculiarities caused by short-range interactions in electrolyte solutions are in most cases closely connected with changes in the microdynamics of the solution. Owing to this fact and to the general importance of dynamic processes, there is an enormous interest in NMR studies of the dynamics of electrolyte solutions.^{7,25} Information about the rotational motion of solvent molecules in solvation complexes comes from solvent relaxation data; translational motions of solvent and ions are observable by PFG spin echo studies.

3.1 Rotational and Translational Motion of Solvent Molecules

When we dissolve a salt in a solvent the relaxation rate of solvent nuclei (e.g. ^1H , ^2H , ^{14}N , ^{13}C , and ^{17}O) is changed as a function of the salt concentration. This change is because a part of the solvent molecules now resides in the solvation spheres of the ions, where the rotational (and translational)

behavior is different from that in the bulk liquid. According to Hertz,^{6,7} one can define coefficients B' and B_D by the following relationships (which correspond to the Jones–Dole equation for the concentration dependence of the viscosity):

$$\frac{(T_1)^0}{T_1(c^*)} = 1 + B'c^* + \dots \quad (4a)$$

and

$$\frac{D^0}{D(c^*)} = 1 + B_Dc^* + \dots \quad (4b)$$

where $(T_1)^0$ and D^0 are the relaxation time and diffusion coefficient in the salt-free solvent, and c^* is the salt concentration on the molality scale. B' and B_D are obtained from the slope of the concentration dependence at $c^* \rightarrow 0$. Positive and negative B coefficients correspond to ‘structure-forming’ and ‘structure-breaking’ salts, respectively. With the convention $B'^{+}(\text{K}^+) = B'^{-}(\text{Cl}^-)$ it is possible to derive single ion $B'^{\pm}$ coefficients and to determine the rotational correlation times $\tau_c^{\pm}$ of the solvent molecule in the ionic solvation sphere:

$$\tau_c^{\pm}/\tau_c^0 = B'^{\pm} \cdot \frac{55.5}{n_c^{\pm}} + 1 \quad (5)$$

when c^* is given in the aquamolality scale. ($D^{\pm}/D^0$ can be obtained in a completely analogous way.) Example data for a number of ions in various solvents are given in Table 1.⁷

For most inorganic ions in water $B'^{\pm} \approx B_D^{\pm}$, showing the same influence of the ion on the rotational and translational motion in its surroundings. However, it seems that this is not true for hydrophobic ions, such as $(\text{alkyl})_4\text{N}^+$ ions. The B' coefficients in aqueous solutions of strong acids (HCl , HBr , HClO_4 , and HNO_3) have recently been measured, revealing a structure-breaking property of the H^+ ion at low temperatures.²⁶

The translational diffusion of water in aqueous electrolyte solutions as a function of salt concentration has been very carefully investigated by the NMR spin echo technique, as shown in Figure 6.⁷ It can be seen that the structure-breaking salts with their large ions increase the translational mobility of water, and there is a strong decrease in the water mobility when, for example, divalent cations are dissolved.

In very concentrated salt solutions (**Concentrated Solution Effects** such as aqueous ZnCl_2 or $\text{Ca}(\text{NO}_3)_2$ solutions, NMR self-diffusion and relaxation measurements revealed that with increasing salt concentration the correlation time ratio $\tau_c^{\text{trans}}/\tau_c^{\text{rot}}$ of translational and rotational motion increases strongly up to a factor of about 7 compared with pure water.⁶ This shows that in hydrous salt melts the degree of freedom for rotational motion of water is about one order of magnitude higher than that for the translational motion.²⁷ The molecular motions of the solvent water in undercooled electrolyte solution has also been extensively investigated,²⁸ as has the pressure dependence of diffusion and solvent reorientation times.²⁹

Figure 6 Self-diffusion coefficients of solvent water (H_2O) molecules in a number of electrolyte solutions as a function of the salt concentration c^* on the molality scale ($T = 25^\circ\text{C}$). (Reproduced by permission of Elsevier Science Publishers from H. G. Hertz, in ‘The Chemical Physics of Solvation, Part B Spectroscopy of Solvation’, ed. R. R. Dogonadze, E. Kálmán, A. A. Kornyshev, and J. Ulstrup, Elsevier, Amsterdam, 1986, Chap. 7)

3.2 Motion of Ions and Complexes

The reorientational motion of ions can serve as a probe of ion–ion and ion–solvent interactions.^{7,25} In polyatomic ions such as ClO_4^- and SO_4^{2-} , the ^{17}O intramolecular QF relaxation can be used.³⁰ In particular, the study of rotational correlation times of solvation complexes of paramagnetic ions has a long tradition in NMR^{5,7,30,31} (see **Paramagnetic Relaxation in Solution and Relaxometry of Tissue**). Measurements of the self-diffusion coefficients $D^{\pm}$ of ions and mobility of ions have become of increasing interest in recent years,^{3,7} and, at least for ionic diffusion in electrolytes, a large amount of data has been collected.³² A relatively young field of NMR is the investigation of electrolytes in the nonequilibrium state, that is in the electrically conducting state, by the DCNMR (NMR in presence of a direct current) technique.^{3,6} This allows measurement of electrophoretic mobilities (see **Electrophoretic NMR**) and transference numbers of distinct ions in complex electrolyte systems.³ Relaxation measurements of ionic quadrupolar nuclei moving in an electric field might yield information

Table 1 The Ratio $\tau_c^\pm/\tau_c^0$ of Rotational Correlation Times of Solvent Molecules in the Solvation Sphere of Ions ($\tau_c^\pm$) and in the Pure Liquid (τ_c^0)⁷ ($T = 25^\circ\text{C}$, $n_c = 6$ was Assumed in All Cases)

about changes in the solvation shell and in the ion–ion distribution function connected with the migration of the ion.³

3.3 Exchange Studies

Exchange studies where the lifetime τ_m of a solvent molecule (or a hydrogen atom) in the solvation complex is the quantity of interest, have an extraordinary importance for the understanding of electrolyte solutions (see *Relaxation Effects of Chemical Exchange*). In particular, the aquo complexes have been studied extensively using ^1H and ^{17}O linewidth measurements,^{6,8} but also many data exist for nonaqueous solvents.⁶ The range of lifetimes τ_m is enormous, a lower limit of about 2 ps can be assumed. A sketch of the lifetimes in aquo complexes is given in Figure 7.³³ The water proton exchange rates in solutions of strong electrolytes have been studied as a function of the pH.³⁴ The mechanism of solvent exchange can be elucidated by pressure dependent ^1H and ^{17}O NMR linewidth studies^{6,35} (see *Kinetics at High Pressure*) and these investigations have contributed enormously to our present knowledge of ligand substitution reactions in electrolyte solutions.

1 INTRODUCTION

Electrophoretic NMR (ENMR) combines pulsed field gradient NMR (PFG NMR) flow measurements with in situ electrophoresis. This arrangement permits the direct measurement of the drift velocities of NMR active ions in electric fields. Furthermore, the selectivity of high-resolution NMR is retained; and, in principle, all the components of a mixture can be detected simultaneously. Therefore, ions can be identified by their NMR spectra and, conversely, NMR spectra of mixtures can be edited on the basis of electrophoretic mobilities. The timescale of a single ENMR experiment, i.e. the ionic drift time, ranges from a few milliseconds to a few seconds. This provides some sensitivity to reaction rates and the ability to determine at least whether exchange reactions occur during the drift time. The disadvantage is that the drift time must be less than T_1 or T_2 , depending on the particular experiment. It is this restricted drift time that limits resolution of drift velocities in ENMR to much lower values than found in classical electrophoresis, e.g. capillary zone electrophoresis (CZE).

In this brief article we present the theory of ENMR at the phenomenological level. The experimental aspects are treated in some detail because the methods and the instrumentation are unfamiliar to most NMR spectroscopists. We also discuss data analysis and display a few examples to illustrate the capabilities and limitations of the method.

2 PRINCIPLES OF ENMR

2.1 Electrophoresis

‘Electrophoresis’ refers to the transport of charged particles in electric fields. In a constant electric field E_{dc} ions of a particular species attain the steady state or terminal velocity $v_e = \mu E_{dc}$, where μ is the electrophoretic mobility. This is of considerable interest in chemistry because the mobility is characteristic of the ionic species in a particular environment. The separation of ions according to mobilities is the basis of analytical electrophoresis. However, general theories relating

μ to molecular properties are complicated and often difficult to use.

Consider a particle of radius a and charge Ze in medium with the dielectric constant ϵ_r and viscosity η . The counterions in the electrolyte, treated as a continuous distribution of charge (ionic atmosphere), effectively screen the charge of the particle so that the effective potential quickly drops to zero with distance. The range of the potential is determined by the inverse Debye screening length:¹

$$\kappa = \left(\frac{2\rho F^2}{\epsilon_0 \epsilon_r RT} \right)^{1/2} I_c^{1/2} \quad (1)$$

where ρ is the density of the solvent, ϵ_0 is the permittivity of vacuum, F is the Faraday constant, R is the gas constant, T is the absolute temperature, and I_c is the ionic strength. It is assumed that κ^{-1} is approximately equal to the thickness of the electrical double layer. With the additional assumption that the applied electric field does not distort the ionic atmosphere, Henry was able to show that the electrophoretic mobility is given by:²

$$\mu = \frac{Ze}{6\pi\eta a} \frac{X_1(\kappa a)}{(1 + \kappa a)} \quad (2)$$

where $X_1(\kappa a)$ is a monotonically increasing function that ranges from 1.0 for $\kappa a \ll 1$ to 1.5 for $\kappa a \gg 1$.

In the ‘small particle’ limit where $\kappa a \ll 1$, equation (2) gives $\mu = Ze/f$, where $f = 6\pi\eta a$ is the Stokes’ law friction factor for a sphere. This result simply expresses the balance of electrostatic and frictional forces at steady state, i.e. $ZeE_{dc} = fv_e$. At the ‘large particle’ limit where $\kappa a \gg 1$, equation (2) is equivalent to $\mu = \sigma/\eta\kappa$, where $\sigma = Ze/4\pi a^2$ is the surface charge density. Also, in this limit Smoluchowski showed that $\mu = \epsilon_0 \epsilon_r \zeta/\eta$, where ζ is the potential at the plane of shear (between the stationary and moving solvent layers).² Thus, in principle, for $\kappa a \gg 1$ a measurement of the mobility provides a direct determination of σ and the ζ potential. It is interesting that in this limit there is no dependence of μ on particle size or even particle shape, but most macroions fall short of this limit and their mobilities show some size dependence.

In fact, applied electric fields can distort the ionic atmosphere, and Henry’s equation is often a crude approximation. However, numerical solutions of the exact equations for flow and ion densities around a sphere, displayed as graphs of mobility versus the ζ potential, confirm that Henry’s formula is accurate for sufficiently small values of the ζ potential.³ Rigorous electrokinetic theories tend to be quite complicated. Modern analytical treatments of this problem have been reviewed by Hunter.^{4,5} A major difficulty with all the theories is that the results are expressed in terms of ζ potentials. The ζ potential cannot be measured, and only in the Smoluchowski limit is it related to measurable quantities. The basic problem is that counterions inside the plane of shear move with the particle and affect the apparent surface charge density. This effect is clearly illustrated by ‘fuzzy’ polymer coatings, e.g. methylcellulose, which displace the plane of shear away from a surface into a region where the ζ potential vanishes. Experimental studies can only hope to relate electrophoretic mobilities to measurable quantities such as diffusion coefficients and, perhaps, estimated surface charge densities.

Analytical applications of ENMR depend on the fact that electrophoretic mobilities of molecular ions and charged molecular aggregates almost always lie in the range from 0 to ± 5 ($\mu\text{m s}^{-1}$)(cm V^{-1}). The applied electric fields are typically 0–100 V cm^{-1} , and the maximum particle displacements in a typical drift time of one second are approximately 500 μm . This is conveniently larger than any particles of interest, but much less than the length of the active volume.

2.2 PFG NMR and the Measurement of Drift Velocities

The measurement of directed flow by means of PFG NMR was first reported by Stejskal.⁶ In this experiment a magnetic field gradient is superposed on the applied magnetic field B_0 , here assumed to be in the z direction. For a gradient of magnitude g in the z direction, the local magnetic field is given by $B = B_0 + zg$, where the origin defines the center of the sample. The simplest description is obtained in a reference frame that rotates at the frequency $\omega_0 = -\gamma B_0$ about the z axis. The pulse sequence in Figure 1(a) shows the 90°_x and 180°_y rf pulses and the gradient pulses of amplitude γg and duration δ . A hard 90°_x rf pulse at $t = 0$ rotates the nuclear magnetization into the y direction. Then under the influence of the first gradient pulse the isochromats precess so that the isochromat associated with the volume element between z and $z + dz$ rotates through the angle $\phi = \gamma g z \delta$ relative to the yz plane in the rotating frame. The net magnetization of the sample in the y direction vanishes and the nuclear spin positions are phase encoded. This is illustrated on the left-hand side of Figure 1(b), where the isochromats, represented by parallel lines after the 90°_x pulse, are wound into a helix of pitch $\Lambda = 2\pi/\gamma g \delta$ by the gradient.⁷ In order to obtain a spin echo, the helix must be unwound. This is usually accomplished by means of a 180°_y pulse, reverses the signs of the x components of the isochromats or, equivalently, sets the phase back by $-2\gamma g z \delta$. Continued precession of the isochromats leads to a refocusing of the phase dispersion resulting from both the applied gradient and the inevitable weak background gradient. The unwinding and echo formation are illustrated on the right-hand side of Figure 1(b).

The first gradient pulse in the Stejskal–Tanner sequence sensitizes the transverse magnetization to translational motion of the spins.⁸ The effect of diffusion is to smear out the helical pattern, i.e. to reduce its amplitude, while flow in the z direction displaces the helix so that an isochromat with $\phi \neq 0$ moves into the plane at $z = 0$. The important point is that the phase of the echo, as shown in Figure 1(b), is $\phi = qv t_1$. A complete description of these effects on the basis of modified Bloch equations gives an expression for the complex magnetization $M_+ = M_x + iM_y$ at the echo maximum ($t = 2\tau$). The phase detected signal can be written as:⁶

$$S(2\tau) = M_0 \exp(-2\tau/T_2) \exp[-Dq^2(t_1 + 2\delta/3)] \exp(iqv t_1) \quad (3)$$

where M_0 is the initial amplitude of the FID, $q = \gamma g \delta$, v is the component of velocity in the z direction (assumed to be nonzero only between the gradient pulses), and D is the tracer diffusion coefficient. Typically, $\delta \ll \Delta$, t_1 and the corrections for δ are unimportant.

Figure 1 (a) The PFG NMR experiment for the measurement of drift velocities, and (b) pictorial representation of phase encoding through the formation of magnetization helices

2.3 One-Dimensional ENMR Experiments

In the simplest ENMR experiment the electric field is applied in the z direction during the time interval between the two gradient pulses in a Tanner–Stejskal spin echo experiment [Figure 1(a)]. If the drift velocity for an ionic species is v_e , the associated magnetization helix is translated through $\Delta z = v_e t_1$ and the phase of the echo is $\phi = qv_e t_1$. Therefore, the measurement of mobility amounts to a determination of the phase shift. If the experiment involves a counterflow of ions as in a U-tube electrophoretic cell or if only the y component of the magnetization is measured, information about the sign of the phase angle is lost and the phase factor must be replaced with $\cos(qv_e t_1)$.⁹ In this case the magnitude of the phase angle can be determined by fitting the echo amplitude to a cosine function with q or E_{dc} as the independent variable. It is sometimes convenient to control E_{dc} by controlling the current I through the sample and making use of the relationship.

$$E_{dc} = \frac{I}{\kappa_e A} \quad (4)$$

where κ_e is the conductivity and A is the cross-sectional area of the cell. Therefore, the attenuation factor associated with electrophoretic drift can also be written as $\cos(q\mu I t_1 / \kappa_e A)$.

The attenuation method was first used in the determination of the electrophoretic mobility of $(\text{C}_2\text{H}_5)_4\text{NCl}$ in D_2O stabilized by a 1 wt % agar gel.¹⁰ The velocities were obtained from graphs of echo attenuation versus gradient duration δ for different potential differences across the electrophoretic cell (giving currents up to 250 mA) as shown in Figure 2. This experiment was performed on ^1H at 28 MHz without resolution of chemical shifts. The salt concentrations ranged up to 0.392 M and typical experimental parameters were:

Figure 2 Signal attenuation versus δ for $(\text{C}_2\text{H}_5)_4\text{NCl}$ in D_2O stabilized by a 1 wt % agar gel

$\Delta = 246$ ms, $g = 15.8 \text{ G cm}^{-1}$, $T = 16^\circ\text{C}$, with currents up to 250 mA. The calculated mobilities were a few per cent lower than literature values for free D_2O solutions as expected from the gel obstruction effect.¹¹

The echo attenuation method is not very accurate for the measurement of small phase angles that are often encountered when (a) the mobility is small, (b) the magnetogyric ratio is small, or (c) the range of useful q values is limited. A more accurate method for determining small phase changes is to measure the shift in the off-resonance echo signal ‘wiggles’ that results from the drift velocity.¹² When the resonance offset $\Delta\omega_{\text{or}}$ is small, i.e. $B_1 \gg \gamma\Delta\omega_{\text{or}}$ and $\Delta\omega_{\text{or}} \gg 2/T_2^*$, the echo signal in the vicinity of 2τ is given by:

$$S(t) \propto \cos(\Delta\omega_{\text{or}}t + \Delta\phi) \quad (5)$$

Here $\Delta\phi$ is zero in the absence of the gradient pulses and becomes $qv_e t_1$ when the gradient pulses are present. Figure 3 illustrates the shift t_s of the zero points when the gradients are applied and inspection shows that $\Delta\omega_{\text{or}} = \pi/t_0$ and that $\Delta\phi = \pi t_s/t_0$. This method provides an accurate determination of the drift velocity when a single resonance line is present, and it has some advantages when extensive signal averaging is required.¹³ However, it provides no information about the distribution of velocities.

Another scheme for measuring the phase of the echo begins with the Fourier transformation (FT) of the echo. A resulting spectral line is ‘phased’ and the parameters are recorded. The procedure is repeated in the presence of the electric field, and the phasing parameters are again determined. The difference between the phasing parameters with and without the drift velocity permits the velocity related phase angle to be estimated. This scheme also permits some frequency resolution since individual well resolved spectral lines can be phased independently.^{14,15}

FT ENMR experiments give full frequency resolution and permit simultaneous measurement of mobilities for all components of a mixture.^{7,16} This is accomplished by Fourier transforming the last half of the echo with respect to t_2 to obtain a set of high-resolution spectra associated with different values of either the duration t_1 or the amplitude E_{dc} of the electric field pulse. In FT ENMR a stack plot of one-dimensional NMR spectra is generated in which, for example,

Figure 3 Two off-resonance echo signals in the presence of flow. (a) Spin echo detected when the gradient was switched off. (b) Spin echo detected when the gradient was switched on

the current is incremented from spectrum to spectrum. In this display of spectra versus current, a peak associated with the i th ionic species is modulated by the factor $\cos(q\mu_i I t_1 / \kappa_e A)$ and the mobility μ_i is obtained from the period of the oscillation (see Section 5, Figure 9).

2.4 Two-Dimensional ENMR Experiments

The FT ENMR experiment generates a two-dimensional data set with intensity versus chemical shift in one dimension and intensity versus either t_1 or the amplitude E_{dc} (or I) in the other. The dependence of the intensity of an NMR line (without spin coupling) on t_1 and E_{dc} is illustrated in Figure 4. This suggests two types of two-dimensional experiment based on the pulse sequence shown in Figure 1(a). The ν_2 (chemical shift) dimension is always obtained by Fourier transformation with respect to t_2 , but the ν_1 dimension can be computed by transformation with respect to either t_1 or E_{dc} , depending on the way in which the experiment is performed.

First, consider an experiment in which τ_1 , τ_2 , and δ are constant and the pulse duration t_1 is stepped through a series of values up to the point where the echo intensity is severely attenuated. Throughout most of this range $t_1 \gg \tau_1$, τ_2 , δ , and

Figure 4 Signal intensity in ENMR versus t_1 and E_{dc}

$t_1 \approx 2\tau$. The attenuation of a spectral line with respect to t_1 for different values of E_{dc} is shown in Figure 4. Fourier transformation with respect to t_1 for every point in the NMR spectrum produces the v_1 or velocity dimension. For the i th ionic species the velocity peaks appears at:

$$v_1^{(i)} = \pm qv_i/(2\pi) \quad (6)$$

and their full widths at halfheight are approximately given by:

$$\Delta v_1^{(i)} = [D_i q^2 + 1/T_2^{(i)}]/\pi \quad (7)$$

Diffusion makes the dominant contribution to the linewidth except when T_2 values are very short. However, polydisperse species may exhibit a range of electrophoretic mobilities at the same chemical shift and therefore contribute to the linewidth. The major disadvantages of this type of experiment are (a) loss of resolution and sensitivity resulting from diffusion and transverse spin relaxation, and (b) interference from J modulation.

In the second type of two-dimensional ENMR experiment all the timing parameters [Figure 1(a)] are held constant. A set of v_2 spectra are obtained as described above, except that E_{dc} (or I) rather than t_1 is incremented. This leads to an important difference. As shown in Figure 4, the intensities oscillate as E_{dc} is increased, but there is no damping. This, of course, implies zero linewidths in the velocity dimension. In simple cases the mobility can be calculated with the equation $\mu = 2\pi/(qt_1 \Delta E)$, where ΔE is the increase in electric field associated with one period of oscillation. However, the transformation of the data set with respect to E_{dc} to generate velocity spectra in the v_1 dimension is not straightforward since the intensity curves are truncated, sometimes severely. This truncation results from the limited range of currents that can be used if heating effects are to be avoided. An exception occurs with some polydisperse samples where intensity versus E_{dc} curves are strongly damped because of a broad distribution of mobilities for ions contributing to the same NMR line (see Section 4.2, Figure 8).

Since Fourier transformation of the undamped but truncated curves yields unacceptable truncation broadening, another kind of transformation is needed. One possibility is the linear prediction (LP) method. On the other hand, damped curves for polydisperse samples can be Fourier transformed without difficulty to obtain the distribution of mobilities. However, the apparent mobility distribution may be distorted because of size dependent damping factors for diffusion and nuclear relaxation. A discussion of data analysis is given in Section 4.

3 PRACTICAL CONSIDERATIONS

The most serious problems associated with NMR in the presence of electrical currents are resistive (Joule) heating and the magnetic field gradients associated with ionic currents. The heating effects are well understood and can be avoided or controlled (see Section 3.1); and, fortunately, the current induced gradients are easy to handle. Holz and Müller¹⁷ have pointed out that current parallel to the main field B_0 makes no contribution to the z component of the magnetic field. This is, of course, the natural configuration for probes

in superconducting magnets. In the event that currents perpendicular to B_0 are present, external compensation of the resulting gradients is possible.¹¹

3.1 The ENMR Spectrometer System

ENMR experiments can be performed with commercial NMR spectrometers equipped with custom built 'gradient' probes.¹⁶ External computer controlled gradient drivers and electric field generators (electrophoresis drivers) are also available. The gradient driver employed in a number of ENMR experiments provided 0–10 A current pulses for 0–13 ms with pulse areas reproducible to 10 ppm.¹⁸ Active feedback was incorporated to ensure constant gradients through continuous current control. A more recent driver provides bipolar pulse capability, pulse programmability on the millisecond timescale, and control of operating parameters by means of a standard MS-DOS compatible personal computer.¹⁹

Gradient amplitudes up to 300 G cm⁻¹ have been used in ENMR. Even at this modest gradient level, eddy currents are induced in metal structures of the magnet and probe; and the resulting slowly decaying magnetic fields can distort NMR signals. It is, therefore, advisable to minimize the eddy currents through careful probe design and the use of actively shielded gradient coils.^{20,21} If these precautions are inadequate, specially designed pulse sequences can be employed to delay data collection until the eddy currents have decayed (see Section 3.4).²² Gradient drivers and probes with shielded gradient coils are now available from a number of vendors.

Homebuilt and commercial power supplies¹⁰ have been used to provide the electrophoresis current. For example a convenient electric field generator has been reported that controls currents from 0 to 10 mA with 2.5 μ A resolution and provides up to 1000 V.¹⁸ This generator is used in connection with electrophoresis cells of the types illustrated in Figure 5(a) and (b), that are designed to fit inside a standard 10 mm NMR probe and to vent bubbles from the electrodes. The U-tube gives a counterflow of ions so that information about the signs of the mobilities is lost. Also, the filling factor is small and shimming can be a problem. The cylindrical design avoids these problems, but is less convenient because of the required gel plug. An alternative cylindrical cell design with a better filling factor but no provision for venting bubbles is shown in Figure 5(c).¹⁵ The glass sieving was added to reduce electro-osmotic flow (see Section 3.3). Platinum, blackened platinum, and Ag/AgCl electrodes have been used by various groups. The latter two types decrease gassing of the electrode.

3.2 Joule Heating and Convection

The heating of samples by electrical currents is a major problem in free solution electrophoresis. Temperature gradients give rise to convection currents associated with Rayleigh–Benard instabilities,²³ and this is especially serious in ENMR where displacements of less than 1 μ m can be detected. The goal is to achieve the highest possible electric field E_{dc} without causing convection currents or otherwise perturbing the system. The power dissipation in the sample

Figure 5 Electrophoretic cells for high-resolution ENMR

resulting from the current I is just I^2R , where R is the resistance, and it is easy to show that the cell develops heat (per unit volume) at the rate:^{16,24}

$$H = \frac{I^2}{A^2\kappa_e} \quad (8)$$

Equations (4) and (8) can be combined to obtain $E_{dc} = (H/\kappa_e)^{1/2}$. Therefore, once the maximum acceptable heating rate has been established, the only way to increase the electric field is to reduce the conductivity. However, experience shows that convection is less of a problem in small bore tubes.

High-resolution ^1H ENMR in free solution is usually performed with currents less than 1 mA in order to avoid heating effects. Therefore, one must often work in the millimolar concentration range to obtain sufficient electric fields. The situation can be improved somewhat by stabilizing samples against convection through the use of dilute gels. In this way, currents up to about 4 mA can be tolerated with only small obstruction effects for small ions.^{11,25}

ENMR studies involving nuclei with small magnetogyric ratios, e.g. $^7\text{Li}^+$ and $^{133}\text{Cs}^+$, present special problems because of low sensitivity and small values of q . Larger sample volumes and higher currents are essential for these experiments to succeed. Holz and co-workers^{10,11,13} have reported various probe and electrophoresis cell designs for low sensitivity nuclei. For example, a probehead insert for an 89 mm superconducting magnet that permits the use of currents to 170 mA for a few seconds is shown in Figure 6.¹³ Temperature gradients are minimized through liquid cooling with Fluorinert FC77 (3M Corp.), and convection is eliminated by the use of gel stabilized samples.

3.3 Electro-osmosis

Consider an electrolyte solution in contact with a charged planar surface fixed in space. Under the influence of an electric field E_{dc} parallel to the surface, the mobile diffuse layer moves and carries the solvent with it. This effect, known as electro-osmosis (EO), provides the pump for capillary zone electrophoresis (CZE),²⁶ but is usually a nuisance for other types of electrophoresis experiment. It can be shown that the steady state velocity of the diffuse layer is given by:^{4,16,27}

$$v_{eo} = \epsilon_r \epsilon_0 \zeta E_{dc} / \eta \quad (9)$$

Figure 6 Probehead for liquid cooled electrophoresis

For a horizontal capillary tube between reservoirs the flow profile may approximate plug flow; but, in a vertical electrophoresis cell, flow along the walls must be compensated by backflow in the center. In fact, it is expected that the velocity profile for ions in a cylindrical tube is parabolic and can be described by:¹⁵

$$v(r) = v_e + v_{eo} \left(\frac{2r^2}{a^2} - 1 \right) \quad (10)$$

where a is the radius of the tube, r is the distance from the center, v_e is the electrophoretic drift velocity, and v_{eo} is the EO velocity close to the wall.

Integration of equation (10) over the cross-sectional area confirms that the average contribution of EO to the ionic drift velocity is zero. Similarly, the contribution to the average phase angle for the spin echo is zero. Therefore, a measurement of the phase angle by a phase sensitive technique in the small angle limit should permit v_e to be measured without interference from EO. The problem is the EO gives a distribution of velocities and may produce severe damping of intensity versus current curves. In the presence of EO, the nuclei between r and $r + dr$ in the sample tube acquire the phase angle $qv(r)t_1$ at the time of the echo and the phase factor in equation (3) must be replaced by:

$$\frac{1}{\pi a^2} \int_0^a e^{iqv(r)t_1} 2\pi r dr = e^{iqv_e t_1} \left[\frac{\sin(qv_{eo}t_1)}{qv_{eo}t_1} \right] \quad (11)$$

Both v_e and v_{eo} are proportional to E_{dc} and they may have similar magnitudes. Therefore, the consequence of EO, described by equation (10), is damping of the intensity versus

current curves in ENMR and loss of resolution in the velocity spectra.

It is best to avoid complications associated with EO. EO always presents a problem with free solution electrophoresis since all surfaces in contact with electrolyte solutions acquire charges. Fortunately, gel stabilized samples are immune to EO since the flow of solvent at the wall is quenched. The standard procedure for reducing or eliminating EO in free solutions is to coat the surfaces with methylcellulose (MW = 110 000) that (a) increases the effective viscosity close to the wall and (b) moves the plane of shear into the region where the ζ potential vanishes.^{16,28} The effectiveness of the coating should be apparent from the amplitude of the solvent (HOD) peak at the highest currents. In the presence of surfactant solutions, the coatings tend to deteriorate with time thus limiting the duration of experiments.

3.4 Dealing with Short T_2 Values and J Modulation

A wide range of T_2 values is found for mixtures containing molecules of different sizes and molecular aggregates. According to equation (3), the amplitude of each line in the ENMR spectra of such mixtures will be attenuated by transverse spin relaxation. For example, in microemulsion solutions the surfactant molecules at the interfaces have short T_2 values, while molecules in the interior of the droplets have long T_2 values. This leads to extremely distorted intensity distributions.²⁹ Also, for protein molecules with molecular weights over a few thousand, the T_2 values for protons are short and approach the rigid lattice limit.¹⁶

Coupled homonuclear spin systems also present problems because of both short T_2 values and J modulation.^{30,31} J modulation arises because the hard rf pulses exchange the spin states of nuclei that are coupled to the nuclei being investigated. This causes the precession frequencies to change so that refocusing of the echo depends on the magnitude of the spin coupling constant J . As a consequence, signals in an FT ENMR experiment may be modulated as τ is increased and may have small or even negative amplitudes.¹⁶

An obvious solution for the problem of short T_2 values is to replace the spin echo (SE) pulse sequence with a stimulated echo (STE) sequence.^{32–34} This causes an immediate loss of a factor of 2 in the signal if $T_1 = T_2$, but large gains can be achieved when $T_1 \gg T_2$. A modified version of the STE sequence is shown in Figure 7, where the first three 90° rf pulses and the fourth and fifth gradient pulses constitute the standard STE diffusion and flow experiment. The first rf pulse rotates magnetization into the xy plane, the gradient pulse phase encodes spatial positions, and the second rf pulse stores the magnetization in the z direction. The transverse components remaining during the interval T after the second rf pulse are eliminated by phase cycling, while the magnetization pattern created in the z direction relaxes by T_1 rather than T_2 processes. The third rf pulse returns magnetization to the xy plane, the following gradient pulse decodes spatial positions, and the STE forms at time $T + 2\tau$ relative to the first rf pulse.

It is advantageous to minimize the time intervals τ in the pulse sequence so that neither the short T_2 values nor the J modulation will affect the amplitude of the STE. The problem is that the gradient pulses induce eddy currents in metal components close to the gradient coils, and in turn the slowly

Figure 7 The LED pulse sequence for ENMR. Phase cycling (ϕ_i values) and homospoil pulses are not shown

decaying eddy currents produce magnetic field gradients that distort NMR signals. The longitudinal eddy current delay (LED) sequence shown in Figure 7 provides a partial solution by storing the STE in the z direction by means of the fourth rf pulse and then recalling the magnetization with the fifth rf pulse after an eddy current settling period.²² The signal is then acquired as a FID. A train of at least three equally spaced gradient prepulses is introduced to insure a steady state response so that the effects of the fourth and fifth gradient pulses will be equal.

The complex data set obtained from either the echo in an STE experiment or the FID in a LED experiment is described by:

$$M_{xy} = \sum_{j=1}^k \exp[i\phi_j(I)] f_j(\tau, T, T_e) \quad (12)$$

where

$$\phi_j(I) = q\mu_j \Delta I / (\kappa_e A) \quad (13)$$

and

$$f_j(\tau, T, T_e) = \frac{M_0^j}{2} \exp \left[-\frac{2\tau}{T_2^j} - \frac{(T + T_e)}{T_1^j} \right] \times \exp \left[-D_j q^2 \left(\Delta - \frac{\delta}{3} \right) \right] \quad (14)$$

With STE the complex signal is acquired from a single half-echo by quadrature detection, while with LED the real and imaginary parts must be acquired in separate experiments in which the fourth rf pulse is phase shifted by 90° . In equation (12) k is the number of species in solution and $\Delta = T + \tau$ is the diffusion or electrophoretic drift time. For the j th species D_j is the tracer diffusion coefficient, μ_j is the electrophoretic mobility, and T_1^j and T_2^j are the spin–lattice and spin–spin relaxation times, respectively. Typically, δ is 1–2 ms and $\tau - \delta$ can be as small as 500 μ s. Therefore, T_2 attenuation and J modulation are usually negligible, and the main concern becomes the relative magnitudes of $T + T_e$ and T_1 .

4 DATA ANALYSIS

Here we are concerned with transformations of intensity versus current data sets to obtain velocity spectra. In the following we assume that the data sets are acquired with

STE or LED pulse sequences. First we note that data sets described by equation (12) contain information about the signs of the mobilities. The signs can be determined for all lines in the ENMR spectrum by means of the reverse precession method.³⁵ With the alternating polarity of the STE experiment this requires the collection of two FIDs (half-echoes), one with positive and one with negative polarity of the electric field. After Fourier transformation with respect to t_2 , the signals with positive and negative polarities can be represented by:

$$S_{\pm}(\omega_2, I) = S_0 \exp[\pm i\phi(I)] f(\tau, \Delta, T_e) [a(\omega_2) + id(\omega_2)] \quad (15)$$

where $a(\omega_2)$ and $d(\omega_2)$ are Lorentzian absorption and dispersion components.³⁶ The combinations $\text{Im}(S_+ - S_-)$ and $\text{Re}(S_+ + S_-)$ give absorption mode spectra that are modulated by $\sin(q\mu\Delta I/\kappa_e A)$ and $\cos(q\mu\Delta I/\kappa_e A)$, respectively. These combinations can be transformed with respect to the current to obtain two-dimensional ENMR spectra that show both positive and negative mobilities.³⁶ The sign of the mobilities can also be obtained from LED data since the phase of the fourth rf pulse can be adjusted to store either the real or the imaginary part of the magnetization.

4.1 Data Inversion for Discrete Samples

The transformation required to convert intensity versus current data sets into velocity spectra depends on the nature of the sample. A discrete mixture, i.e. one that contains a small number of monodisperse components, gives a data set that can be described by equation (12). As discussed in Section 2.4 and illustrated in Figure 4, the data set at each chemical shift (ν_1) is described by a truncated cosine function or perhaps a sum of truncated cosine functions. In this situation the linear prediction (LP) method is an attractive alternative to the FT.^{37,38} LP extends truncated data sets and can generate frequency spectra from incomplete sets. The LP procedure assumes that the data set y_n can be represented by a finite sum of damped sinusoids of the form:

$$y_n = \sum_{j=1}^k I_j \exp(-\gamma_j n \tau) \exp(-i\omega_j n \tau + i\phi_j) \quad (16)$$

where I_j , γ_j , ω_j , and ϕ_j are the intensity, damping factor, frequency and phase, respectively, of the j th component, and τ is the time step. The determination of the best values of these parameters makes use of two least squares procedures and one polynomial rooting, thus avoiding the slow iterative nature of other curve fitting techniques. When the best set of intensities, frequencies, damping factors, and phases has been determined, a frequency (velocity) spectrum can be synthesized from these parameters.^{25,39} Various versions of LP have been implemented for spectroscopic applications, but the only one used in ENMR to date is LPZOOM, that was developed by Tang and Norris.⁴⁰ The LPZOOM program permits the user to specify a range of frequencies and thus to perform localized analysis with a reduction in computational time.

Figure 8 Signals versus current for three groups of protons on glucose molecules entrapped in vesicles

4.2 Data Inversion for Polydisperse Ions

Micelles, vesicles, and biological cells exhibit continuous distributions of electrophoretic mobilities. Often the chemical shifts for certain groups, e.g. phospholipid headgroups in vesicles, are relatively independent of the size of the aggregate, and peaks are found in the FT NMR spectrum that have contributions from a wide range of mobilities. In such cases the signal versus current curves show considerable damping. An example is shown in Figure 8 for glucose entrapped in charged phospholipid vesicles.⁴¹ The sample was prepared with 30 mM total lipid and the mole ratio of L- α -lecithin (egg) (EPC) to L- α -dioleoylphosphatidylglycerol (DOPG) sodium salt was 4 : 1. At pH 7, where the EPC headgroup is neutral and the DOPG headgroup is negative, the vesicles are charged. The data were acquired in an STE experiment and the parameters were: $\tau = 20$ ms, $\Delta = 420$ ms, $q = 1.870 \times 10^3$ cm⁻¹, $\kappa_e = 0.049$ mS cm⁻¹, and $A = 0.0909$ cm².

For the description of damped interferograms the discrete summation in equation (12) must be replaced with an integral over the distribution of mobilities. Thus:

$$S(I, \nu_2) = S_0(\nu_2) \int_{-\infty}^{\infty} g(\mu, \nu_2) f(\tau, T, T_e) \times \exp[i(q\Delta)I\mu/\kappa_e A] d\mu \quad (17)$$

where $S_0(\nu_2)$ is the intensity in the absence of the current, $g(\mu, \nu_2)$ is the normalized distribution function for the mobility, and the relaxation factor $f(\tau, T, T_e)$ is defined in equation (14). We note that the signal amplitude is just the cosine FT of the distribution product $G(\mu, \nu_2) = g(\mu, \nu_2) f(\tau, T, T_e)$ and, therefore, that this product can be obtained by the inverse Fourier transform (IFT) of $S(I, \nu_2)$ with respect to the current. In the special case that the relaxation factor $f(\tau, T, T_e)$ is approximately constant over the range of integration, the IFT yields the distribution function $g(\mu, \nu_2)$ directly. This condition may be satisfied for solute molecules entrapped in the aqueous cavity of large vesicles ($a > 0.2$ μ m) when $q^2\Delta < 3 \times 10^6$ s cm⁻² and the nuclear relaxation times are also relatively insensitive to changes in size. However,

Figure 9 FT ENMR spectra of a mixture containing surfactants and TIPB in D₂O

in general, the apparent distribution function is weighted by the relaxation factor. This opens the possibility of relating mobilities to particle sizes by obtaining $G(\mu, \nu_2)$ with different values of q . In principle a plot of $\ln[G(\mu, \nu_2)]$ versus q^2 should give the diffusion coefficient associated with μ , but it must be kept in mind that the resolution of mobilities is determined by the range of current values, i.e. the duration of the interferogram $S(I, \nu_2)$.

5 ILLUSTRATIONS OF ENMR SPECTRA

High-resolution ENMR experiments have typically been performed with low ionic strengths and small diameter electrophoresis cells in order to obtain high electric fields with low currents. An example is provided by a microemulsion sample with microdroplets of oil in water (o/w). Surfactant molecules form the surface of the droplets with their hydrophobic tails extending into the oil. Both T_1 and T_2 are long for hydrocarbon (oil) protons in the droplets, but the surfactant protons exhibit a range of T_2 values. The spectra in Figure 9 were obtained by means of the simple SE experiment (Figure 1) for a sample prepared with 0.15 mL triisopropylbenzene (TIPB), 0.165 mL CH₃(CH₂)₁₁(OCH₂CH₂)₄OH (Brij 30), 0.075 g sodium dodecyl sulfate (SDS), and 20 ml D₂O.¹⁶ The sample was equilibrated, and then the translucent o/w microemulsion layer was separated and diluted by a factor of 6 with D₂O. The measured conductivity was $\kappa_e = 0.106$ mS cm⁻¹ at 25 °C, and the experimental parameters were $q = 686$ cm⁻¹, $t_1 = 0.41$ s, and $2\tau = 0.42$ s; and the current ranged from 0 to 0.9 mA.

The peak height versus current plots shown in Figure 10 can be fitted to cosine functions to obtain the mobilities. This procedure yields $\mu = 3.4 \times 10^{-4}$ cm² V⁻¹ s⁻¹ for both the TIPB and the surfactant peaks, indicating that these components move together in the microemulsion droplets. This experiment illustrates T_2 attenuation since a major signal from the hydrophobic end of Brij 30 has completely relaxed to zero. J modulation is also illustrated by the inverted TIPB(2) signal, and the partial attenuation of the HOD signal at 0.9 mA shows the onset of electro-osmosis.

Figure 10 Peak heights versus current for the spectra in Figure 9: (□) HOD, (Δ) CH₃ in TIPB, (○) ϕ H in TIPB, (●) S

The spectrum in Figure 11 illustrates mobility ordered two-dimensional NMR (MOSY) for a sample containing tetramethylammonium ion (TMA) (2.00 mM) with mixed micelles [1.50 mM SDS and 4.00 mM octaethylene glycol dodecyl ether (C₁₂E₈, with E = C₂H₄O)].^{25,39} In its present form this method provides resolution of about one part per hundred in mobilities and permits the signs of the mobilities to be determined. The STE pulse sequence was used in this experiment, and the experimental parameters were: $q = 722$ cm⁻¹, $\Delta = 0.400$ s, $A = 0.0986$ cm², and $\kappa_e = 0.273$ mS cm⁻². The current was limited to 0.75 mA to avoid heating effects, and the severely truncated data sets were transformed by means of LPZOOM, as discussed in Section 4.1. The mobilities indicated by the peak maxima are 2.75×10^{-4} and -1.55×10^{-4} cm² V⁻¹ s⁻¹ for protons in TMA and micelles, respectively. Note that the peak at 3.51 ppm is associated with C₁₂E₈ and its position on the mobility axis shows that this neutral compound migrates with the micelle. This ability to identify molecular species and to detect their interactions in solution is a major strength of MOSY. In this example the different ionic species have different chemical shifts. When

Figure 11 Mobility ordered two-dimensional NMR spectrum of tetramethylammonium ions and mixed micelles

there is overlap, the LPZOOM program has limited ability to separate components on the basis of their mobilities if the mobilities are quite different and the truncation is not too severe.²⁵

6 LITERATURE SOURCES

Electrophoretic NMR up to 1989 has been reviewed by Johnson and He¹⁶ and more recently two-dimensional ENMR has been reviewed by Johnson.⁴² ENMR has also been reviewed by Holtz.⁴³ NMR methods for the measurement of diffusion and flow have recently been covered by Callaghan in a monograph on NMR microscopy.⁴⁴ Also, NMR flow measurements have been reviewed by Caprihan and Fukushima.⁴⁵

An introduction to electrophoresis and electrokinetic effects can be found in the textbook on macromolecules by Tanford² and in the biophysical chemistry text by Cantor and Schimmel.⁴⁶ A more complete treatment of electrokinetic effects can be found in the monographs by Hunter.^{4,5} Also, an accessible discussion of electro-osmosis and other surface phenomena is available in Adamson's textbook on the physical chemistry of surfaces.²⁷

Reviews of electrophoretic light scattering (ELS) are also relevant since similar experimental problems are encountered in that field. In particular we note a somewhat dated review of ELS by Ware⁴⁷ and a recent monograph by Schmitz⁴⁸ which treats electrokinetic effects as well as experimental techniques. Holographic relaxation spectroscopy (HRS) combined with electrophoresis also has features in common in ENMR.^{49,50}

1 INTRODUCTION

Soils are heterogeneous mixtures of organic substances, minerals and organomineral complexes. The organic substances include macromolecules lacking well-defined structures or repeating units. The minerals include poorly ordered or amorphous matter. These difficulties have hindered scientific studies of soil, leaving fundamental questions of structural chemistry open to debate until recent years. NMR spectroscopic studies have provided some convincing answers that broaden our understanding of the origins of soil characteristics, the influences of land management on soil fertility, and the fate of agrochemicals.

Soil organic substances were extracted, methylated, and dissolved in deuterated solvents for the earliest ^1H and ^{13}C NMR studies of soil chemistry.¹⁻³ These studies provided little worthwhile information. Much more detail emerged from a 1976 paper describing ^{13}C NMR spectra of soil organic substances in alkaline aqueous solution.⁴ The first ^{13}C CP MAS NMR spectrum of whole soil was published in 1981.⁵ The publication rate has now risen to an average of about one paper per month describing ^{13}C CP MAS NMR studies of humic substances. Solution ^{13}C NMR spectroscopy is used on occasions, and several other nuclei provide useful spectra.

This article is not intended as a comprehensive review. More complete references to relatively early work can be found in two books published in 1987.^{6,7}

2 SAMPLE PREPARATION

Soil organic substances are commonly separated into three fractions defined in terms of solubility. 'Humic acids' are not soluble in water under acid conditions, but are soluble under alkaline conditions. 'Fulvic acids' are soluble under all pH conditions. 'Humins' are not soluble under any pH conditions.

Humic acids generally account for the major part of soil organic matter. They have been characterized by CP MAS NMR or dissolved in aqueous alkali for solution NMR, the two procedures yielding similar patterns of signal intensities.^{8,9} Fulvic acids are hygroscopic and yield poor CP MAS NMR spectra unless they are carefully dried.¹⁰

Differences between ^{13}C CP MAS NMR spectra of humic acids and the corresponding humins are not as pronounced as might be expected for separation based on differences in chemical properties.^{11,12} It appears that differences in solubility are rather caused by differences in physical accessibility of the organic matter.¹¹ The NMR spectra of fulvic acids are usually distinctly different from the corresponding humic acids or humins,^{11,12} so humic acids are not representative of the organic matter in the complete soil.

Soil extracts can be used for NMR studies without fractionation into humic and fulvic acids. This procedure is particularly advisable in preparing samples for ^{31}P NMR,¹³ since phosphate esters could be hydrolyzed under the acidic conditions required for precipitation of the humic acid fraction. Sequential extraction procedures have been developed to remove over 80% of organic phosphorus from soils for solution NMR characterization.¹⁴

Removal of paramagnetic species such as Fe^{3+} can improve ^{13}C CP MAS NMR spectra of solid soils and humins.¹⁵⁻¹⁷ As a general rule, the ratio $\text{C}:\text{Fe}; >> 1$ is required for a good spectrum.¹⁵ Pretreatment by a mixture of HCl and HF has the added advantage of removing inorganic substances and therefore concentrating the organic matter.¹⁷

3 SIGNAL ASSIGNMENTS FOR ^{13}C

A typical CP MAS NMR spectrum of whole soil (Figure 1) shows overlapping signals that are grouped in four chemical shift ranges for discussion here.

Signals in the range $\delta = 10-50$ are assigned to alkyl carbon, including side chains in amino acids, structures derived from higher-plant polymers such as cutins and suberins, and structures formed by cross-linking between polyunsaturated

Figure 1 Carbon-13 CP MAS NMR spectrum (50.3 MHz) of Taupo Soil, A horizon: 7 mm diameter cylindrical rotor spun at 5.0 kHz, 1 ms contact time, 15 ms data acquisition time, 300 ms pulse delay, 10.6 h of data accumulation

microbial lipids.¹⁸ Input from microbial activity has been demonstrated by incubating soil with ^{13}C -labeled glucose.¹⁹ A signal near $\delta = 31$ is sometimes relatively strong in spectra of soil fractions sieved to select particles with dimensions less than $2\ \mu\text{m}$.^{20–22} This signal has been assigned to polymethylene chains, including organo-clay complexes.²⁰

Signals in the range $\delta = 50$ – 110 are assigned primarily to *O*-alkyl carbon, i.e. oxygen-substituted carbon in alcohols and ethers, including plant carbohydrates and their degradation products. These substances are relatively abundant in fractions sieved to select coarse particle sizes,²² and are particularly well preserved in cold climates.²³ This chemical shift range includes signals between $\delta = 50$ and 60 assigned to *N*-substituted carbon in amino acids.⁴

Signals in the range $\delta = 110$ – 160 are assigned primarily to aromatic carbon. The question of whether aromatic substances form a major or minor component of soil organic matter has been debated as recently as 1985.^{24,25} Perhaps the best answer is that considerable variation has been observed. A band centered on $\delta = 130$ is particularly prominent in NMR spectra of organic matter found in soils that have been affected by fire.^{26,27} Signals in the range $\delta = 150$ – 160 have been assigned to oxygen-substituted aromatic carbon. The degree of oxygen substitution shows a strong negative correlation with soil development, perhaps as a result of selective degradation of the more highly substituted structures.²⁸

Signals in the range $\delta = 160$ – 210 are assigned to carbonyl carbon.²⁹ This region is usually dominated by a peak in the region $\delta = 170$ – 180 , assigned primarily to carboxylic acids. Secondary amides can also contribute to the peak.³⁰ The signal strength is usually stronger than would be expected from chemical analyses for carboxylic functional groups, and nitrogen contents fail to account for the discrepancies. Schnitzer and Preston concluded that 'it is possible that chemical methods do not react stoichiometrically with materials of high molecular weight, such as humic substances, because of steric factors.'²⁹

4 SIGNAL ASSIGNMENTS FOR OTHER NUCLEI

Poor signal dispersion has discouraged widespread use of ^1H NMR in soil science. Bands of partly resolved signals have been observed in the ranges $\delta = 0.8$ – 2.5 (alkyl), 3.3 – 3.8 (*O*-alkyl), and 6 – 8 (aromatic).³¹ Features within these bands have been assigned to more specific chemical structures.³² Aromatic protons can exchange with deuterons in solvent, resulting in underestimation of aromaticity.³³

After ^{13}C , ^{31}P is the nucleus most commonly used in NMR studies of soil. Some generalized signal assignments are shown in Figure 2. The sample was chosen for the diversity of chemical species. The orthophosphate monoesters include choline phosphate ($\delta = 3.5$) and inositol hexaphosphate (four signals).¹³ Orthophosphate diesters include phospholipids. Phosphonates are clearly distinguished by the chemical shift range characteristic of a direct carbon–phosphorus bond. This category includes phosphonolipids ($\delta = 20$) and their degradation products ($\delta = 18$).¹³ Many ^{31}P NMR spectra of pasture soil extracts show only a dominant signal near $\delta = 5$, assigned to inorganic orthophosphate, with a weaker band across the range $\delta = 3$ – 5 , assigned to orthophosphate

monoesters.³⁴ Some spectra of soil extracts include a signal near $\delta = -21$, assigned to polyphosphate chain units.¹³

The natural abundance of ^{15}N is so low that isotopic enrichment is necessary. Soil organic matter matures over periods of centuries, so only the first steps of humification can be studied by monitoring the fate of ^{15}N -enriched additives. At least three different chemical shift scales have been used in studies relevant to agriculture. The chemical shifts mentioned here are expressed in parts per million to high frequency from ammonia. Typical values are $\delta = 30$ – 70 for amine nitrogen, 90 – 120 for amide nitrogen, and $\delta > 120$ for heterocyclic nitrogen.³⁵ Chemical shifts have been reported for a number of specific substances considered relevant to the chemistry of humic substances.³⁵ When a soil humic acid was incubated with ^{15}N -enriched NaNO_3 , the ^{15}N CP MAS NMR spectrum of the product was dominated by a broad band at $\delta = 119$, assigned to secondary amides, e.g. in proteins.³⁶ The ^{15}N CP MAS NMR spectra of composts prepared with ^{15}N -enriched plant material are dominated by a peak assigned to proteins, with weaker signals at 83 and 71 ppm assigned to nucleic acids.³⁷

NMR is not normally the technique of choice for studies of inorganic matter in soil, but there have been exceptions.

Most soil silicates contribute ^{29}Si NMR signals in a broad band across the region $\delta = -80$ to -115 .³⁸ Fractionation of a soil into particle size ranges has been used to demonstrate the predominance of quartz ($\delta = -113$) in a coarse fraction, and layered aluminosilicates ($\delta = -92$) in a fine fraction.³⁹ One of the hydrated aluminosilicates, imogolite, contributes a relatively narrow peak at a distinctive chemical shift of $\delta = -78$.³⁸ Therefore, ^{29}Si NMR can be used to estimate the imogolite content of soil.

Solution NMR methods have been used to characterize aqueous ^{27}Al in plugs of soil.⁴⁰ Most of the signal strength was

Figure 2 Phosphorus-31 NMR spectrum (32.2 MHz) of an aqueous NaOH extract from Carrick tussock-grassland soil. Sample mixed with D_2O in a 10 mm tube; $12\ \mu\text{s}$ pulse width, $0.8\ \text{s}$ data acquisition time with proton decoupling, $5.0\ \text{s}$ pulse delay without proton decoupling, $79\ \text{h}$ of data accumulation. The soil properties are described elsewhere⁴³

found in a band from $\delta = -9$ to 12. This band was assigned to species with octahedral coordination, including complexes with humic substances. A relatively sharp peak at $\delta = 63.5$ was assigned to a polynuclear cation, believed to be more toxic to plants than the mononuclear cation.⁴⁰

5 RELIABILITY OF NMR RESULTS

Patterns of relative signal areas have been compared for ^{13}C NMR spectra of extracted humic substances run as solids and as solutions.^{8,9,41} The overall similarities have been encouraging, but sources of errors have been identified in both techniques.

In the case of solution NMR spectroscopy, it is necessary to choose a pulse delay that is adequate for both T_1 relaxation and suppression of NOEs. Preston and Blackwell drew attention to the need to consider magnetic field strength in selecting a suitable pulse spacing.⁸ Values of $T_1 < 0.2$ s have been reported for protonated carbon in solutions of humic substances run at a field strength of 1.87 T,⁴² but values in the range 0.2–0.8 s have been reported for experiments at 5.6 T.⁸ These observations are consistent with molecular motion including components with correlation times longer than required for the T_1 minimum. Values of NOEs are particularly low and values of T_1 are particularly long for carboxyl carbon, so the content of this chemical functional group can be underestimated unless the decoupler output is gated off during the pulse delay.^{8,42} A dramatic improvement in the strength of these signals has been reported for pulse delays increased from 0.5 to 5.0 s.⁴¹ A pulse delay of 2 s has been suggested for solution ^{13}C NMR at 63 MHz.⁸ Pulse delays as long as 20 s have been found necessary in ^{31}P NMR of soil extracts.⁴³

The choice of magnetic field strength should be considered in ^{13}C CP MAS NMR also. Fründ and Lüdemann reported $T_1(\text{H})$ values in the range 3–6 ms for humic matter run at 2.35 T, rising to the range 10–20 ms for the same sample run at 7.05 T.⁴¹ These values are fortunately all so short that the pulse spacing is more likely to be determined by the duty cycle of the spectrometer. It is important that the contact time should be long enough for adequate cross polarization, yet short enough to avoid the effects of variations in $T_{1\rho}(\text{H})$ between chemical functional groups. These two criteria conflict for most humic substances. On one hand, contact times as long as 1 ms are needed to achieve maximum signal strength for nonprotonated carbon, e.g. carboxylic carbon.⁸ On the other hand, values of $T_{1\rho}(\text{H})$ can vary between chemical functional groups, because of the heterogeneous nature of soil organic matter. This was particularly evident in a clay fraction, where values of $T_{1\rho}(\text{H})$ ranged from 2.0 ms for *O*-alkyl carbon to 6.2 ms for *O*-substituted aromatic carbon.⁴⁴ Variations in $T_{1\rho}(\text{H})$ can arise, e.g. from selective binding of metal ions to specific chemical structures.⁴⁵ A contact time of 1 ms seems to provide a reasonable compromise.⁴⁵

Paramagnetic ions such as Fe^{3+} can shorten values of $T_{1\rho}(\text{H})$ until organic matter in the immediate vicinity of each ion no longer responds to CP MAS NMR.⁴⁶ Interference from organic free radicals is not as important, as shown by a 'spin counting' experiment in which 97% of carbon in a solid ash-free fulvic acid responded to CP MAS NMR, despite the presence of organic free radicals.⁴⁶

6 APPLICATIONS

Soils are often classified according to their color, so studies of the origin of color can provide a fundamental basis for classification schemes. NMR experiments have shown that the more intensely colored humic and fulvic acids contain relatively high proportions of aromatic carbon.^{26,47} Humic substances in general display strong absorbance in the UV, tailing off across the visible region. Absorptivity at 272 nm has been found to be highly correlated ($r = 0.94$) with the strength of ^{13}C NMR signals assigned to aromatic carbon in humic acids.⁴⁸ Weaker correlations have been reported for fulvic acids.⁴⁹

CP MAS NMR has been used to demonstrate a correlation ($r = 0.997$) between the aromatic carbon content of humic acids and the partition coefficient for binding of pyrene.⁵⁰ This suggests that the chemical structure of humic material should be considered in any attempts to model the transport or fate of organic pollutants. Carbon-13 NMR has been used to demonstrate formation of covalent bonds between ^{13}C -labeled 2,4-dichlorophenol and humic acid.⁵¹ Decreased herbicide activity in tilled soil has been attributed to the organic matter being in a more reactive state than in soil that was not tilled.⁵² The ^{13}C NMR spectrum of humic acid from the tilled soil showed a relatively strong band assigned to aromatic carbon, but the authors advised caution in the interpretation of the results, in view of the small magnitude of the observed differences and the small number of samples tested.⁵²

A combination of ^1H , ^{13}C , and ^{31}P NMR has been used to monitor degradation of a herbicide, glyphosate (*N*-phosphonomethylglycine), in soil.⁵³

Fecal fibre is rich in carbohydrates, particularly crystalline cellulose, contributing relatively sharp ^{13}C NMR signals across the region assigned to *O*-alkyl carbon.⁵⁴ These signals become weaker when feces are composted. In the case of composts formed from cattle manure, the relative signal area of the *O*-alkyl band dropped from 59% to 33% over a period of 147 days of composting.⁵⁵ CP MAS NMR has been described as the 'most quantitative procedure' of those tested for use in characterizing compost maturity.⁵⁶

Intensive land management practices are known to cause long-term decreases in soil organic matter. Carbon-13 NMR has been used in attempts at characterizing the residual organic matter. Divergent results indicate a complex dependence on the nature of the initial material and details of the management regime. Oades et al. found relatively high aromaticity in a red-brown earth cultivated for 60 years, compared with undisturbed soil.⁵⁷ On the other hand, Schulten et al. found relatively low aromaticity in soils cultivated for periods up to 35 years.⁵⁸ Schulten et al. found lowest concentrations of residual organic matter in soils treated with high doses of mineral fertilizers. It is possible that their results reflect the influence of fertilizers rather than the influence of crops. Preston et al. observed a decrease in the area of the *O*-alkyl band and a corresponding increase in the area of the alkyl band in CP MAS NMR spectra of peat cultivated for periods up to 15 years.⁵⁹ These changes may reflect the influence of plowing, exposing organic matter to biological oxidation. Skjemstad et al. studied soils cultivated for periods up to 45 years.⁶⁰ They found no detectable changes in relative signal areas across CP MAS NMR spectra, but the signals became broadened in the spectra of soils with the lowest concentrations of residual

organic matter. They suggested that a major mechanism for the relative stability of persistent soil organic matter may be a physical association with the inorganic component. The effects of cultivation are also evident in ^{31}P NMR spectra of soil extracts, the diversity of chemical species being greater in uncultivated soils than in corresponding samples of cultivated soils.⁶¹

Several authors have studied the influence of climate and vegetation on soil properties. A negative correlation ($r = -0.998$) has been found between rainfall and the strength of ^{13}C signals assigned to aromatic carbon in humic acids.⁶² The ^{31}P NMR spectra of soil extracts show a particularly wide diversity of chemical species for sites with high annual precipitation.⁴³ No correlations were found in a study of vegetation and its influence on the chemical structure of soil.⁶³

7 SEPARATING OVERLAPPING SIGNALS

The applications sketched above have been hindered by problems with overlapping signals, particularly in solid state ^{13}C NMR. Most authors describe soil organic matter in very general terms, e.g. distinguishing 'aromatic' or 'aliphatic' carbon. Some spectra show hints of variations in details within one or more of the bands. Several strategies have been suggested for separating these overlapping signals.

Dipolar dephasing suppresses CP MAS NMR signals from most CH and CH_2 groups, leaving signals assigned to nonprotonated carbon or protonated carbon in functional groups with some freedom for internal motion. This technique has been used to demonstrate differences between the degrees of aromatic substitution in different humic acids.⁶⁴

Proton spin relaxation editing exploits the heterogeneous nature of soil.⁶⁵ A proton inversion–recovery pulse sequence is combined with ^{13}C CP MAS NMR. Linear combinations of partly relaxed and fully relaxed spectra are generated to separate subspectra assigned to distinctly different forms of organic matter with distinctly different values of $T_1(\text{H})$. This procedure has been used to separate subspectra from the CP MAS NMR spectrum of a humic acid, suggesting that material extracted from clays may differ from material extracted from other soil fractions.²⁸ Variations in $T_{1\rho}(\text{H})$, mentioned above, could also be used for separation of subspectra.

2D NMR techniques show some promise for separation of overlapping signals. A ^1H – ^{13}C heteronuclear chemical shift correlation experiment has been used to construct a 2D NMR plot for a sample of fulvic acid, with the ^1H CRAMP spectrum on one axis and the ^{13}C CP MAS spectrum on the other.⁶⁶ This showed that a broad band in the CRAMP spectrum could be assigned to a mixture of contributions from alkyl and *O*-alkyl structures, with the latter offset to slightly higher chemical shifts.

Despite this progress, the problem of separating overlapping signals remains one of the greatest challenges in NMR studies of agricultural and soil samples.

1 INTRODUCTION

Coal has been used as an important source of fuel for thousands of years, but it is a complex, heterogeneous fuel which is difficult to burn or process without serious environmental implications. Coals can vary significantly among different geographic areas in important properties such as rank, ash, sulfur and nitrogen content, mineral impurities, and maceral constituents. Substantial worldwide attention is being focused on more efficient and cleaner methods for utilization of this important energy resource.

The wide heterogeneity of coal has made it difficult to characterize and to correlate its structure. Evidence exists that differences in geological histories and maceral constituents affect coal chemistry and technological applications of coals, since coals of the same apparent rank but of different geological history can exhibit a variety of physical and chemical properties. Coal structure varies with recognizable geological and geochemical features which affect its reactivity. The variations in the geochemical history and the complexities of the macromolecular structure of coal further confound a clear understanding of the complex nature and interrelationships among coals.¹

Our understanding of the details of coal structure has improved markedly over the last decade. Coal is now believed to be a heterogeneous mixture composed of a macromolecular network of varying degrees of cross-linking within the macromolecular phase with a smaller molecular phase imbibed or associated with this network. A major portion of the credit for the present state of knowledge of the general characteristics of coal structure can be traced to studies that employed NMR spectroscopy. It is interesting to observe that NMR was first applied to the study of coals in 1955,² only nine years following the discovery of the NMR phenomenon in bulk matter. These first NMR observations employed broadband ¹H techniques which, in the absence of means to reduce the large proton dipole-dipole interactions, produced very broad bands in fossil fuel related materials. In 1968 Haeberlen and Waugh³ demonstrated that the hydrogen dipole-dipole interaction could be significantly reduced by averaging in spin space via a multiple pulse approach⁴ rather than attempting to spin the sample mechanically at very high MAS rates in order to achieve the same results. In the mid-1970s Schnable⁵

and Gerstein et al.^{6,7} demonstrated that if the sample is spun simultaneously about the magic angle then the chemical shift anisotropy (CSA) as well as the inhomogeneous heteronuclear dipolar interactions are simultaneously averaged. Hence, much narrower peaks are obtained with this experiment which Gerstein named CRAMPS. The proton CRAMPS experiment was first applied to coals by Gerstein in 1981.⁸ The CRAMPS experiments have been especially useful as a probe to study the 'mobile phase' present in coal structure wherein solvents such as perdeuterated pyridine are imbibed into the parent coal.⁹⁻¹³ The reduction in proton NMR linewidths is attributed to motional narrowing and to reduction of bulk and molecular susceptibility anisotropies by partial mobilization of certain structural moieties in coal caused by disruption of hydrogen bonds and other noncovalently bonded structural units.

As early as 1966 the first ¹³C NMR spectra appeared of materials derived from coal.¹⁴ Broadline ¹³C NMR spectroscopy was first applied to whole coals in 1971 to confirm the high aromaticity of anthracite.¹⁵ Significant improvements in resolution began to emerge five years later¹⁶ with the application of the cross polarization technique followed by applications of magic angle spinning to coal.¹⁷ In 1979 Opella and Frey¹⁸ introduced the concept of the dipolar dephasing experiment which discriminates between nonprotonated and protonated carbons by means of the effective C-H dipole-dipole interaction. Alemany et al. studied the characteristics of the dipolar dephasing experiment on model compounds¹⁹ and then demonstrated the utility of this experiment in a careful study of an Illinois No. 6 coal.²⁰ Work by Wilson,²¹ Murphy,²² and Gerstein²³ and their co-workers has verified the value of dipolar dephasing experiments in the study of coal. The data derived from the techniques described, together with others to be described in subsequent sections, have been extremely valuable in probing the general structural features of coals and have greatly enhanced the usable knowledge base for improved coal utilization.

2 EXPERIMENTAL TECHNIQUES

Since the organic constituents of coal are composed primarily of hydrogen and carbon with smaller amounts of oxygen, nitrogen, and sulfur (typical elemental compositions of a lignite, high volatile bituminous, and anthracite coal are C₁₀₀H_{78.9}N_{1.4}S_{0.4}O_{22.7}, C₁₀₀H_{76.2}N_{1.7}S_{0.4}O_{6.1}, and C₁₀₀H_{17.5}N_{0.7}S_{0.2}O_{1.5}, for the Beulah-Zap, Pittsburgh No. 8, and Buck Mountain, respectively) (see Section 5), NMR experiments have focused primarily on ¹H and ¹³C applications. While ¹H NMR experiments (particularly the CRAMPS applications) have added valuable insight for coal structural studies, the major area of interest has been in the elucidation of the carbon skeletal structure since many of the questions regarding the physical and chemical properties can be addressed from a clear understanding of the details of the carbon backbone and associated functional groups. Carbon-13 NMR spectroscopy has become one of the premier tools in organic structure analysis due to the relationship between the local electronic environment of the carbon nucleus and the ¹³C chemical shift and, hence, the use of ¹³C NMR techniques has become essential for the study of solid carbonaceous materials such as coal chars, pitches, and geochemical materials in general.

2.1 CP MAS and Isotropic Shifts

The combination of cross polarization and magic angle spinning has been used to obtain high-resolution NMR spectra from solids for many years. Magic angle sample spinning at a rate greater than the chemical shielding anisotropy (CSA) of the carbon nuclei will average the principal values of the chemical shift tensor (δ_{11} , δ_{22} , δ_{33}) to the isotropic chemical shift value. Linewidths obtained by CP MAS experiments are typically of the order of 1–2 ppm in simple organic compounds but relaxation effects (T_2), anisotropy in bulk susceptibility, crystallinity, and solid state effects can considerably broaden the individual spectral lines. In some cases one may observe multiple lines due to lattice structures that contain multiple structures per unit cell or crystal lattice effects that impose a preferred conformation which breaks the local symmetry. In general, the solid state isotropic chemical shifts are similar to those in solution and the appropriate chemical shift/structure relationships developed in solution studies may be used to interpret solid state CP MAS spectra.

The Utah group^{24,25} illustrated the relationship between isotropic chemical shifts and the CP MAS spectra of coals. While coal spectra are characterized by banded structures in the aliphatic and aromatic regions, it is evident from the bandshapes and shoulders on these bands that structural information is available beyond that obtained from aromaticity considerations only. Gerstein demonstrated that isotropic chemical shifts could be used to look .. ‘beyond just aromaticity; chemical functionality’.²⁶ An example of the diversity of the ^{13}C NMR spectra of coals is presented in Figure 1 for a series of coals of ranks ranging from lignite through anthracite.

Solum et al.^{27,28} have used a rather detailed isotropic chemical shift distribution together with dipolar dephasing data to obtain 12 structural parameters for the coals contained in the Argonne Premium Coal Sample Bank. Wilson et al.²⁹ and Hatcher et al.³⁰ have used isotropic ^{13}C NMR data to propose chemical transformation pathways for coal precursors, while Hatcher et al.³¹ have used such data to construct a three-dimensional computer simulation of coal formation from components of plant precursors. Hence, CP MAS chemical shift data have had a major impact in geochemical applications in general and fossil fuels in particular.

2.2 Shielding Tensors and 2D Methods

The CSA is a reflection of the interaction of the electronic environment of the nuclei with the external magnetic field. Depending on the orientation of a given molecule in the field, a different value of the chemical shift is observed. If the sample simultaneously exists in all possible orientations (as in the case of a powder sample), a superposition of all the possible shift values for the nuclei in the molecule is observed. The frequencies obtained from the breakpoints or discontinuities of this powder pattern are the principal values of the chemical shift tensor. For a ^{13}C nucleus in an anisotropic environment, three distinct values are observed, and these values correspond to the three elements (δ_{11} , δ_{22} , δ_{33}) found as the diagonal elements of the chemical shift tensor. From the study of single crystals, both the principal values of the shift tensor and their orientation in the molecular framework can be determined.

Figure 1 CP MAS spectra of the Argonne Premium Coals plus the Buck Mountain anthracite (PSOC-1468). The data were acquired as described by Solum et al.^{27,28} Coal rank increases from bottom to top in the figure

Single crystal studies of aromatic compounds show that δ_{33} is always perpendicular to the plane of the aromatic ring³² and its value in the aliphatic region reflects its independence of the π system. The other two tensor components, δ_{11} and δ_{22} , are oriented in the plane of the aromatic system. Theoretical studies have placed δ_{11} nearly perpendicular to the C–C bond with the largest π -bond order in all of the polycondensed aromatic hydrocarbons studied.³²

Orendt et al.³³ have provided a brief description of experimental methods for studying chemical shift tensors in model compounds and coals. Extracting principal values from powders is extremely difficult due to the inherent low resolution of the experiment. Hence, principal values can normally be obtained only for very simple compounds or compounds of high symmetry containing only two to three tensors. The variable angle sample spinning (VASS) technique improves the resolving capacity to only three to four tensors.³⁴ Yet the information provided by CSA data is very valuable in the study of small molecules and even relatively large systems such as naphthalene, pyrene, hexahydropyrene, pyracene, and coals.^{33,35} The data obtained on such systems have demonstrated that the shape of the tensor patterns can be used to distinguish different types of carbons in an environment where spectral overlap might preclude identification based on isotropic chemical shift information. This is particularly advantageous for coal due to spectral overlap in both the aromatic and aliphatic regions. Due to the large range in the principal values of the chemical shift tensors in aromatic carbons, an effort to obtain such data on coals is most fruitful since the carbon backbone of coals is dominated by aromatic species.

Table 1 Average Chemical Shift Tensor Values for Aromatic Carbons^a

Carbon type	δ_{11}	δ_{22}	δ_{33}	δ_{av}
Protonated (75)	207 $\pm$ 22	146 $\pm$ 19	18 $\pm$ 12	124 $\pm$ 11
Substituted (21)	226 $\pm$ 11	165 $\pm$ 15	23 $\pm$ 14	138 $\pm$ 8
Phenolic (16)	227 $\pm$ 16	163 $\pm$ 9	72 $\pm$ 3	154 $\pm$ 6
Condensed (7)	205 $\pm$ 2	195 $\pm$ 2	-72 $\pm$ 5	133 $\pm$ 2

^aThe numbers in parentheses following the carbon type are the number of measurements considered in the analysis. Errors represent standard deviations of available data. All values are given in parts per million. The first three lines of data are from T.M. Duncan, 'A Compilation of Chemical Shift Anisotropies', Farragut Press, Chicago, IL, 1990, p. C-5. The data on condensed carbons come from data obtained at the University of Utah.

For convenience, the aromatic carbons in coal can be grouped into four categories: protonated, substituted (having an alkyl group substituent), phenolic (having a hydroxy or ether substituent), and bridgehead or condensed. Presently available chemical shift tensor data on these types of carbons are summarized in Table 1 while Figure 2 portrays the ideal lineshapes for the four types of carbon of interest. These ideal lineshapes were obtained by tabulating literature values for the shift tensor components for aromatic carbons in simple organic compounds measured by a variety of methods.³²⁻³⁷ These data have been used to study the aromatic structure in a fusinite maceral, two anthracite, and three bituminous coals.^{33,35}

A detailed description of methods for obtaining chemical shift tensors is contained elsewhere (see *Chemical Shift Tensors*). Hughes et al.³³ have used a static chemical shift-chemical shift correlation spectroscopy experiment (referred to as the 2D flipper experiment) to examine the chemical shift tensor patterns in a medium volatile and a low volatile bituminous coal. In a conventional 1D static solid state spectrum of coal, a large degree of overlap between aromatic and aliphatic signals occurs, whereas the 2D chemical shift-chemical shift correlation spectrum clearly separates the two spectral regions and exhibits the presence of multiple overlapping chemical shift tensors in both the aromatic and aliphatic regions of both samples. Furthermore, this separation of spectral regions allows for the determination of the aromaticity from a non-MAS spectrum. The aromaticity values (f_a) are 0.78 for the Upper Freeport and 0.87 for the Pocahontas No. 3 coals compared with values of 0.81 and 0.86 determined by CP MAS experiments.^{27,28}

In an effort to address the problem of spectral overlap many 2D techniques have been developed to obtain a spectrum with an isotropic shift along one axis and a stationary or slow-spinning sideband powder pattern along the other. One such technique, the triple echo magic angle turning (triple echo MAT) experiment (see *Magic Angle Turning and Hopping*), has proven to be especially effective for studying model compounds and has been used to examine a number of coals, including those in the Argonne Premium Coal Sample Bank,³⁸ a naphthalene-derived pitch, a semi-anthracite, and an anthracite coal.³⁹ The chemical shift tensor patterns taken at various isotropic shift values in coals clearly exhibit the presence of the characteristic shapes of the chemical shift tensors of protonated, substituted, phenolic, or bridgehead carbons and, hence, one is able to distinguish different types of carbons in broad spectral regions where it is impossible to

**Figure 2** Ideal tensor patterns and average isotropic shifts for the four types of aromatic carbons in coal: (a) protonated, (b) alkyl substituted, (c) condensed or bridgehead, and (d) phenolic

distinguish individual lines. An example of the deconvolution of overlapping lines is given in Figure 3, where the slice taken at an isotropic chemical shift value of 124 ppm is shown for Pocahontas No. 3 low volatile bituminous coal.⁴⁰

The simulation of the individual powder patterns for an axially symmetric aromatic tensor and an overlapping protonated tensor are compared with the experimental data in Figure 3. A modified version of the triple echo MAT experiment called PHORMAT (see *Magic Angle Turning and Hopping*), which incorporates rotor pulse synchronization, has been used in a blind comparison of the tensor principal values obtained from single crystal data in methyl α -D-glucopyranoside.⁴¹ The principal values for the six carbons in this model compound have an rms average distance of 0.57 ppm from the tensors determined from the single crystal data, while the estimated variation in the principal values of the tensors studied with the triple echo MAT experiment vary by approximately 2 ppm.⁴⁰ Hence, the principal values reported by the Utah group have been shown to represent faithfully the single crystal data within 2 ppm when the triple echo MAT experiment is used, and an error of 0.5–1 ppm is expected if the more precise rotor pulse synchronized PHORMAT experiment is used. A remarkably good correlation is also obtained between the carbon aromaticities (ratio of

Figure 3 Spectral slice taken at an isotropic chemical shift of 124.5 ppm from the triple echo MAT experiment on Pocahontas No. 3 coal obtained from the Argonne Premium Coal Sample Bank. The experimental data were simulated as the superposition of protonated and condensed (bridgehead) aromatic carbon tensor patterns, labeled theoretical, which is overlaid on the experimental trace

aromatic to aromatic plus aliphatic carbons) determined from variable contact time CP MAS data and the triple echo MAT experiment. This relationship is shown in Figure 4 for the coals in the Argonne Premium Coal Sample Bank, two anthracites and a methylnaphthalene-derived pitch (correlation coefficient $R^2 = 0.991$), demonstrating that the slow spinning triple echo MAT experiment does not lead to any apparent distortions of the structural components in coals.

3 DESCRIPTION AND CONSTITUENTS

3.1 General Nature of Coals and NMR Parameters

Coal is a complex sedimentary rock derived from plant remains. During the coalification process the accumulated plant material underwent differing degrees of chemical decomposition and depolymerization. These degradation processes formed peat which was subsequently transformed into coal of different ranks and properties based on sedimentary input, local environment, depth of burial, and local geological history. These various local conditions combined to produce a material that can be quite variable in terms of elemental composition and the nature of the inorganic materials incorporated into the coal material either as mineral inclusions or as chemically bound species. The elemental composition (particularly

Figure 4 Comparison of aromaticity values for the Argonne Premium Coals, two anthracite coals (PSOC-867 and PSOC-628), and a methylnaphthalene-derived pitch. The CP MAS data were obtained as described by Solum et al.^{27,28} while the MAT values were obtained from the triple echo MAT experiment (see *Magic Angle Turning & Hopping*)

hydrogen, oxygen, and carbon) of the organic material can be used in a general classification scheme for describing the rank of a coal which, in increasing order, is given as peat, lignite, subbituminous, high volatile bituminous, medium volatile bituminous, low volatile bituminous, semianthracite, anthracite, and meta-anthracite. This rank progression exhibits a general order where the atomic ratios H/C and O/C decrease with increasing rank.

The most uniform microscopic constituents of coal, whose morphologically preserved or repolymerized materials retain distinct characteristics, are known as macerals. A large number of macerals have been identified and named. All macerals, however, can be conveniently grouped into three major subdivisions; liptinite, vitrinite, and inertinite. The vitrinite group of macerals are thought to be derived from plant cell wall material and make up the majority (50–90%) of most North American coals. The liptinite group of macerals is derived from algae and/or the resinous and waxy parts of plants such as resin, spores, pollen, and cuticles. These materials make up 5–15% of most North American coals but can be considerably higher in other coals and in coals derived from unique depositional environments. These macerals are the most aliphatic and hydrogen-rich of all the maceral groups. The inertinite group of macerals is derived from degraded woody tissue, making up 5–40% of most North American coals, but in western Canada and all southern hemisphere coals the percentage can be considerably higher.

The carbon aromaticity, f_a , is an important parameter in the study of coal and coal-derived materials and is the most widely used NMR parameter for coal studies. The first serious applications of ^{13}C NMR experiments to coal were directed at determining the carbon aromaticity. While several investigators studied a wide range of coals, Maciel et al.⁴² and Gerstein et al.^{23a} were the first investigators to investigate systematically the aromaticity/rank relationship. Gerstein et al. compared ^{13}C NMR-derived aromaticities with those obtained

Figure 5 Carbon aromaticity, f_a , as a function of carbon content on a dry, ash-free basis

indirectly from graphical densities. The relationship between carbon aromaticity and rank (as derived from % carbon) is given in Figure 5. In NMR studies of macerals, the general trend in f_a values is lignite < vitrinite < inertinite. Early studies by Maciel et al.⁴³ and Zilm et al.⁴⁴ helped to define the variations in aromaticity in the different maceral groups as well as the apparent differences in chemical functionality arising from differences noted in the isotropic shift/intensity distributions. More detailed NMR studies of maceral groups helped to refine the range of variations in aromaticities and chemical functionality.^{25,45,46}

The quantitative accuracy of the f_a values derived from CP MAS experiments has been questioned and this controversy is addressed by Botto et al.⁴⁷ (see *Fossil Fuels*). Orendt and co-workers have demonstrated that quantitative accuracy is obtainable if the CP MAS data are taken carefully with a variable contact time experiment and the data fitted to the proper model.²⁸

3.2 Structural Components

The description of coal as a macromolecular network is credited to van Krevelen⁴⁸ who proposed a gel/sol model. The tools of polymer chemistry have been applied to study coal and advanced characterization techniques such as ¹³C NMR have assisted in defining the parameters of the macromolecular structure of coals. The current model for coal structure consists of clusters of aromatic and hydroaromatic ring systems that are cross-linked such that domains exist which can, in some cases, undergo rapid reorientational motion. The argument that supports a cross-linked macromolecular network, other than the fact that the bulk of coals are not soluble in common solvents, is that coals swell by as much as 250% when brought into contact with appropriate solvents. The degree of reversibility is also consistent with a covalently cross-linked structure and rules out entanglements as the only associative force. Coals also display viscoelastic properties which are consistent with a macromolecular structure.

The type and characteristic of the second phase or component of coal is not as well defined as the macromolecular network, and has been the subject of extensive debate.⁴⁹ The 'mobile components' observed in proton NMR experiments have been shown to be complex and their relationship to a trapped molecular phase is yet to be completely resolved. Two views have been taken regarding the 'mobile protons' observed in ¹H NMR experiments. The first is that these protons can be attributed to molecules that are free to rotate in cages of the macromolecular network, and the second is that the mobile protons are associated with fragments of the macromolecular network capable of rotation due to single C–C or C–O bonds linking such fragments to the network. Jurkiewicz et al.^{12,50} have used proton CRAMPS techniques to examine carefully the nature of the mobile protons in coal by comparing the native Argonne Premium Coals with those imbibed with pyridine-*d*₅. In pyridine-saturated coals the aliphatic and aromatic protons are better resolved and more structural details are evident. In addition, imbibing the samples with pyridine dramatically changes the structural or dynamic characteristics of a coal. The CRAMPS data provide a rough correlation between proton mobilities and the extractable components of coal. Employing a careful pyridine extraction study, Fletcher et al.⁵¹ have studied the ¹³C NMR structural components of the extracts and residues from the Argonne Premium Coals and contrasted the subtle differences between the extractable and residual components in terms of cross-linking between aromatic clusters.

An excellent review of the molecular structure, chemistry, and existing structural models of coal (up to 1986) is given by Davidson.⁵² The early coal structure models proposed by Given and Weiser⁵³ and further refined by Shinn and Solomon⁵³ were based, in part, on available NMR data. From these models investigators attempted to construct an average or representative macromolecular structure of coal. In general, the information used for assembling a coal structure is molecular weight, aromatic cluster size, linkages between aromatic units, carbon aromaticity, elemental composition, as well as experimental results from chemical and thermal reactions. In order to explain the physical properties of coal and the thermal and chemical behavior of coal, network models have recently emerged^{54–57} and solid state NMR data have become indispensable in constructing models that describe coal behavior.^{51,54–57}

4 APPLICATIONS TO COAL SCIENCE

4.1 Refinements in Structural Detail

Gerstein suggested that ¹³C NMR spectroscopy could provide more information on coal structure than just aromaticity and demonstrated that one could use dipolar dephasing techniques to examine functional groups and estimate aromatic cluster size.²² Alemany et al.^{19–21} refined the functionality studies employing painstakingly acquired dipolar dephasing data. Solum et al.^{27,28} carefully employed a variety of experiments (i.e. dipolar dephasing, variable contact time experiments, and integrations of the ¹³C spectra over selected chemical shift ranges) to derive 12 structural parameters for the eight

Figure 6 (a) Aromatic carbon structure distribution of the Argonne Premium Coals; (b) structural distribution of carbons associated with oxygen in the Argonne Premium Coals; and (c) carbon distribution of the aliphatic region of the Argonne Premium Coals

Argonne Premium Coals as well as a large variety of other coals and coal-derived chars.^{51,56,57} The traditionally defined carbon aromaticity, f_a , is a sum of the contributions of all sp^2 carbons to an NMR spectrum. In coal samples it is assumed that ethylene groups are not present in any significant quantity. Hence, the f_a values are assumed to consist of aromatic plus carbonyl groups and these parameters have been redefined as f_a' and f_a^C , respectively. Employing lengthy dipolar dephasing experiments, the relative contributions of protonated and non-protonated aromatic carbons can be estimated as f_a^H and f_a^N , respectively. The nonprotonated aromatic carbons, f_a^N , consist of contributions from alkyl-substituted, oxygen-substituted (phenols and phenolic ethers), and bridgehead carbons, defined as f_a^S , f_a^P , and f_a^B , respectively. The aliphatic groups have been segregated by chemical shift ranges which can be used to approximate the contributions from methyl groups, f_{al}^* , oxygen-substituted alkyl carbons, f_{al}^O , and f_{al}^H , which is defined as the sum of all CH, CH₂, and nonprotonated aliphatic carbons. While these parameters are derived from chemical shift ranges that are known to contain some overlap with other functional groups, these approximations are reasonable and can be used to develop approximate model structures that

Figure 7 Plot of the mole fraction of bridgehead carbons, χ_b , versus C where C is the number of carbon atoms per aromatic cluster. The solid curve is for the combined model, the upper dashed curve is for the circular catenation model, and the lower dashed curve is for the primary catenation mode. (See Solum et al.²⁷ for details)

are consistent with other analytical data. The major structural parameters derived from the coals in the Argonne Premium Coal Sample Bank plus Buck Mountain anthracite are given in Figure 6. From a knowledge of the relative number of peripheral and bridgehead carbons, it is possible to estimate the average aromatic cluster size of coal samples.²⁷ The average cluster size model for coal is shown in Figure 7 and the range of average number of aromatic carbons per cluster (AC/CI) is given in Figure 8. This parameter has proven extremely useful in analyzing changes that occur during conversion and combustion processes.

If one defines the total number of ring attachments as the number of alkyl and oxygen substituents on the average aromatic cluster, it is possible to estimate the number of attachments per cluster. This number is between three and six for all coals studied but small variations in this parameter, defined as the cluster coordination number ($\sigma + 1$), are very important in explaining phenomena associated with coal structure, physical properties, and combustion behavior. The cluster coordination numbers for the coals previously described are given in Table 2.

4.2 Applications to Combustion and Pyrolysis Modeling

As previously discussed, the present model for coal structure is based on a network consisting of aromatic clusters of varying size connected by various types of bridging groups, and a simple schematic of the major types of structural elements that can be derived from NMR data is shown in Figure 9.

Figure 8 Aromatic cluster size of the Argonne Premium Coals and Buck Mountain anthracite, PSOC-1468

^aThe Advanced Combustion Engineering Research Center (ACERC) selected a set of standard coals for characterization and combustion testing and modeling. The 11 coals consist of the eight coals contained in the Argonne Premium Coal Sample Bank and three additional coals obtained from the Penn State Coal Sample Bank. Column headings are defined in the text.

^bAveraged over two or more sample vials.

A number of investigators have applied statistical methods to predict how such a network would behave when subjected to thermally induced bridge-breaking cross-linking and mass transport processes. The geometry of a network is described by its degree of branching. An unbranched linear network will have one bridge per ring cluster attaching it to the next cluster. Thus, each cluster has two attachments and is said to have a coordination number ($\sigma + 1$) of two. A highly branched network would have several bridges attached to it and a higher coordination number. When coal is heated, the connecting bridges can break and new bridges can form. The objectives of network models of coals are, given the geometry

Figure 9 Representative chemical structural units identified in ^{13}C NMR analysis of coal and coal chars

of the macromolecular network, to predict the concentrations of individual aromatic ring clusters (monomers) and linked clusters (oligomers of n clusters, ' n -mers') that are completely detached from the totally linked network, as a function of the number of unbroken bridges. By assigning an average or distribution of molecular weights to the ring clusters, the amounts of tar, extractables, liquids, or char can then be defined from the distribution of oligomer sizes. The application of network models appears to unify many observations of coal pyrolysis, including tar formation, extract formation, metaplast formation, fluidity, and solvent swelling behavior.⁵⁴

A major challenge to all network models is the acquisition of analytical data that describe the network with sufficient detail that the investigator is not required to make guesses or fit the experimental data in order to derive critical network parameters. Grant et al.⁵⁵ have demonstrated that the coal macromolecular structure can be modeled as a Bethe lattice and that this lattice structure can explain the nonlinear behavior associated with devolatilization processes of coals. The coordination number of the Bethe lattice, $\sigma + 1$, is a key element in predicting the lattice behavior, and this parameter is determined directly from NMR data as the average number of substituents on an average aromatic cluster. Four other essential parameters, P_o , BL , MW , and m_δ , can be derived from the NMR data of coals.

The fraction of intact bridges between clusters, P_o is calculated with the assumption that all nonbridging cluster substituents are terminated by a methyl group and can be estimated as

$$P_o = [(\text{attachments}/100\text{C}) - f_{\text{al}}^*]/(\text{attachments}/100\text{C}) \quad (1)$$

While it is recognized that aryl-aryl bridges and phenolic groups are present in relatively small amounts in most coals, these structural units cannot be easily derived from NMR data and, hence, this approximation neglects hydroxy and aryl groups as possible chain terminators. The remaining cluster attachments must be either aliphatic or ether bridges between different clusters or aliphatic loops between two adjacent carbons in the same aromatic cluster, i.e. a hydroaromatic structure such as exists in tetralin. The number of bridges and loops, BL , on a cluster is defined as

$$BL = P_o \times (\sigma + 1) \quad (2)$$

The mechanical properties of the network will be related to this parameter because BL is related to the cross-link density of the macromolecular structure. The average cluster molecular weight (MW), and the total mass of the attachments to the aromatic cluster (m_δ) are

$$MW = (\text{aromatic carbons/cluster} \times 12.011) / (f_{a'} \times \%C) \quad (3)$$

$$m_\delta = (MW - C_{\text{clust}} \times 12.011) / (\sigma + 1) \quad (4)$$

where C_{clust} is the average number of carbons per cluster. While these parameters fall within certain ranges (see Table 2), each coal is unique and must be modeled separately.

During coal devolatilization, both tar (defined as volatiles, other than water, that condense at room temperature) and gas (CH_4 , CO , CO_2 , H_2O , light hydrocarbons, etc.) are released and a residual char remains. Employing the NMR-derived parameters needed to model the macromolecular network of each coal, it is possible to predict the tar and total mass loss (tar plus gas) of a set of coals with reasonable accuracy, as seen in Figure 10, without the necessity of invoking fitting parameters.

The mass of attachments to the aromatic ring is directly related to the amount of gas liberated during coal devolatilization through thermal cracking of the side chains.⁵⁷ During the pyrolysis process the physical and chemical properties of the residual char are continually changing. Solum et al.⁵⁶ were able to follow the details of the release of tar and gas together with the evolution of char structure from a lignite (Beulah-Zap) and a high volatile bituminous (Illinois No. 6) coal during devolatilization. The NMR data were used to track the lattice parameters associated with average cluster size and cross-linking reactions. Under rapid heating conditions (10^4 K s^{-1}), the data demonstrate that Zap coal undergoes early cross-linking behavior due to the loss of carboxy groups whereas Illinois No. 6 exhibits a slower overall rate of cross-linking. It was further noted from the NMR data that the number of cluster attachments remained constant during mass release

during rapid pyrolysis at a temperature of 1250 K. However, near the end of the mass release the number of bridges and loops increased, suggesting that the coal lattice had begun to cross-link as tar release was terminated but as gas release continued. Under rapid heating but short resident time conditions in the reactor employed, the data exhibited little evidence of cluster size growth in the macromolecular structure. These data suggest that near the end of the devolatilization process cross-linking occurs at the same time as aliphatic carbons are released and the graphitization process does not occur under the conditions of the experiments performed. In the Illinois No. 6 coal, most of the mass loss occurred before the onset of significant changes in aromaticity. For the Zap coal, the changes in aromaticity occurred much earlier than for Illinois No. 6. The carbon skeletal structure of the final chars are similar for these two coals and Fletcher et al.⁵⁷ have reported similar results on a number of other chars even though the structure of the initial coals are quite different.

The physical properties of the macromolecular structure are related to the extent of cross-linking present. The NMR-derived bridges and loops parameter can be used estimate the degree of cross-linking that exists in coals and chars. An NMR cross-link index can be defined as

$$\text{NMR index} = (M_\infty - M_T) / (M_\infty - M_0) \quad (5)$$

where M_T is the number of bridges and loops per cluster at temperature T and the 0 and ∞ subscripts refer to the parent coal and the fully pyrolyzed char respectively.

Figure 11 compares the cross-link density obtained from the ^{13}C NMR data with that obtained from solvent swelling experiments.⁵⁷ These data clearly demonstrate that the functional form of the NMR cross-linking index is consistent with the normalized volumetric swelling index commonly used to study the cross-link structure in polymers. In the Beulah-Zap lignite, the number of bridges and loops increase with temperature, indicating that initial cross-linking has occurred at a relatively low temperature ($\sim 500 \text{ K}$) and progressive cross-linking occurs as the temperature increases. In the case of the Pittsburgh No. 8 coal, the NMR data suggest that the initial solvent swelling behavior is due to the breaking of labile bridges at moderate temperatures (500–600 K), which permits increased flexibility of the macromolecular network. At higher temperatures ($>700 \text{ K}$), the number of bridges begins to increase as the swelling of the coal decreases. Such behavior would be expected as a more rigidly cross-linked network developed. The NMR data confirm that low-temperature cross-linking occurs in low-rank coals and that cross-linking at moderate temperatures is observed in both bituminous and low-rank coals.

The preceding examples demonstrate that NMR spectroscopy provides a great deal of information on coal structure and is perhaps the premier analytical tool in coal studies despite the inherent difficulties in carrying out experiments and interpreting the quantitative nature of the data. Even so, data carefully taken can be used to assess differences that occur in coals and follow many processes associated with coal utilization. Ambiguity exists in extracting information from overlapping spectral bands in both the aromatic and aliphatic regions. However, promising new experiments, such as the triple echo MAT and PHORMAT, that take advantage of the information contained in the chemical shift tensors, will probably resolve

Figure 10 Comparison of predicted and measured tar and total volatiles yields for a wide range of coals. Data are for coals from the Argonne Premium Coal Sample Bank and from the Penn State Sample Bank for which NMR and pyrolysis data are available. (See Solum et al.⁵⁶ for details)

Figure 11 Comparison of the normalized volumetric swelling ratio (NVSR) for Beulah-Zap lignite and Pittsburgh No. 8 with the ^{13}C NMR index derived from the number of bridges and loops present in the parent coals and the pyrolysis chars. (See Solomon et al.⁵⁴ for details)

some of these ambiguities, particularly those associated with the aromatic region of the spectra.

5 NOTE

Beulah-Zap and Pittsburgh No. 8 are from the Argonne Premium Coal Sample Bank, while the Buck Mountain anthracite is available from the Penn State Sample Bank as PSOC-1468.

1 INTRODUCTION

Energy¹ is an important commodity because it affects our lives in many ways. In the past, a direct relationship had been drawn between energy consumption and economic growth. Advancement in economic growth was shown to have a favorable impact on the quality of life in economically advanced societies by fostering better health and educational services, a robust industrial base with which to sustain future development, and various forms of labor-saving devices for common use. Often concerns about the negative impacts from economic growth, such as pollution, overpopulation, and crime have been neglected by nations striving to improve their economic status.

In the rapidly changing world of the last 20 years, however, there have been escalating demands placed on global energy resources. An ever-increasing number of developing countries have competed for the existing energy supply. Environmental issues have become the highest priority in guiding the utilization of global resources. While traditional 'old-world' fuels such as wood, agricultural products, and animal dung are still in use around the globe, they remain effective sources of energy only for less developed societies. Alternative energy resources in the form of geothermal and hydroelectric power are limited throughout the world, while renewable resources such as solar, wind, and tidal have been slow to develop on a large commercial scale. Development of nuclear energy, once heralded as the answer to meet the future global energy demands into the next millennium, has been severely curtailed because of apprehension about radioactive release into the environment and problems in storage of high level radioactive wastes. Consequently, a greater burden of world energy demands over the past 20 years has centered on fossil fuels. With increasing demands on supplies worldwide, fuel quality has diminished significantly. In addition, utilization of fossil fuels as a carbon source for the production of bulk and specialty chemicals, and of high technology polymer blends and composites may be almost as important economically as their use as an energy source.

Fossil fuel energy resources include coal, peat, petroleum, oil shale, tar sands, and natural gas. Total world resources of coal are 15.1×10^{12} ton; total world production is estimated to be 3.0×10^9 ton per year. The importance of coal as a resource is that, despite having greater problems with production, transportation and utilization compared with oil and gas, it

represents a vast resource to meet energy demands well into the future (for more than 1000 years). World resources of peat, being far less utilized than the other fuels, is estimated to be only 0.2×10^{12} ton. Estimates of the reserves and resources of petroleum, having received considerable attention because of concern over their eminent depletion globally, are on the order of 0.3×10^{12} ton, of which about 0.1×10^{12} ton are proven reserves. Worldwide oil production is about 4×10^9 ton per year. Enhanced oil recovery strategies have added approximately an additional 0.1×10^{12} ton to the estimate of total recoverable resources of petroleum. Tar sands are fairly localized throughout the world, with estimated reserves of only 0.03×10^{12} ton. On the other hand, oil shale deposits are widely distributed geographically and represent a potentially enormous resource, with estimates ranging between 100×10^{12} and 500×10^{12} ton of potential oil. Limitations for the commercialization of this vast energy resource are the large-scale operations required for production and hence prohibitive investment costs, and the severe environmental problems that would be created by the massive excavation of natural lands and subsequent disposal of enormous quantities of solid waste. Natural gas, with proven reserves similar in energy equivalence to those of petroleum, has the advantage of being the cleanest of the fossil fuels; however, transportation costs of this commodity between continents are high unless supplies can be reached economically via pipeline.

Applications of NMR spectroscopy to the study of fossil fuels have experienced extraordinary growth since the inception of the technique in 1946.²³ Early experiments focused on the application of broadband ¹H NMR spectroscopy to petroleum, oil shale, and coal research. High-resolution liquid state ¹H NMR proved to be an extremely useful structure elucidation tool for fuel extracts and solubilized conversion products in subsequent years. However, NMR did not flourish as a celebrated technique for fossil fuel characterization until the 1970s. The growth of the technique was brought about by several factors: (1) integration of computers with instrumentation in the late 1960s enhanced data acquisition capabilities considerably; (2) introduction of Fourier transform methods paved the way for the development of pulsed NMR spectroscopy, which made detection of less sensitive nuclei more routine, and spawned a wide variety of pulsed techniques for sensitivity enhancement, relaxation measurements and multidimensional NMR studies; and (3) the oil embargo of 1973–74 and the Organization of Petroleum Exporting Countries (OPEC) incident in 1979 catalyzed abrupt increases in the price of petroleum, reversing the trend of cheap and abundant energy supplies that had lasted over the past 100 years. This incident prompted general concern over the availability of energy resources in the future and, as a consequence, stimulated growth of basic and applied research in the area of fossil fuels to seek alternate forms of energy. Nearly two decades of intensive research in NMR characterization of fossil fuels ensued.

2 APPLICATIONS TO COAL SCIENCE

Coal⁴ is considered to be a heterogeneous organic rock and is typically black in color, although geologically younger deposits can range in color from brown to brownish red. It is formed by the accumulation of plant debris which has been

altered over geological time by the action of biological, chemical, and physical (heat and pressure) degradation processes. The relative quantities of remaining plant parts, and the degree of their thermal maturation and degradation result in coals with varied properties. Coals may be classified as banded (humic coals) or nonbanded (cannel or boghead coals), are hard or soft, or can vary in rank from brown coal, through lignite, subbituminous, bituminous to anthracite. The degree of thermal maturation of plant matter, or coalification, is referred to as *rank*.

The evolution of coal, the enormous variation found in its composition, its microheterogeneity, and its differentiation toward chemical reactions suggest that coal is a complex mixture of compounds. While this is true, however, there is some order to its inherent, overall structure. There are microscopically discrete, optically homogeneous aggregates of organic materials derived from various plant parts that constitute coal. These individual domains are referred to as *macerals*.^{5,6} There are three major maceral groups, each having their own distinct set of properties and selective chemistries. The most abundant of the macerals found in US coals is *vitrite*, which is derived from woody tissue of plants and is a largely lignin based polymer. The group of macerals called *liptinite* may be derived either from waxy leaf cutin, parts of spores and pollen, or algal bodies. This group of macerals tend to be composed of highly aliphatic material. The last maceral group, *inertinite*, named for its relative unreactivity in most chemical reactions, is thought to be derived from material that has undergone extensive oxidation or that is a form of fossilized charcoal derived from primordial forest fires. The inertinite macerals have a high degree of aromatic character.

Apart from the organic components, there may be substantial quantities of water and mineral matter present in coal. The minerals can be varied and also rather complex in composition; hydrated aluminosilicates, clay minerals, quartz, sulfides, sulfates, pyrite and carbonates have been identified, to name a few. The main elemental constituents of coals, therefore, are carbon, hydrogen and oxygen, with varying amounts of nitrogen and sulfur, and lesser amounts of silicon, calcium, aluminum, iron, magnesium, sodium, and other trace elements. Given this diversity of chemistry and elemental composition, coals have been a rich source for study by NMR techniques.

2.1 Structure Characterization

2.1.1 Liquid State NMR

The first published account of high-resolution ^1H NMR of a coal liquid, or soluble reaction product, appeared in 1959.⁷ This first ^1H spectrum (Figure 1) of a coal asphaltene recorded in carbon disulfide at 125°C demonstrated that the technique could readily distinguish three magnetically inequivalent types of proton nuclei in the sample, and confirmed that few polynuclear aromatic structures were present. This was the first definitive structural information obtained on a fossil fuel material. Two years later, the first liquid state ^1H NMR spectrum of a coal extract was reported. Since that time, numerous workers have reported on similar studies involving

Figure 1 The first proton NMR spectrum of an asphaltene in carbon disulfide at 125°C. Recorded by J. N. Shoolery, H. E. Weaver, and R. C. Jones at Varian Associates

coal extracts and have demonstrated the utility of the technique for analyzing the hydrogen distributions in these materials.⁸

In 1960, Brown and Ladner⁹ were the first to demonstrate that the hydrogen distribution in carbonaceous fuels determined by ^1H NMR could be used to infer information about the carbon skeleton. Initial experiments were performed on a series of vacuum carbonization products from coals. The method used information from the ^1H NMR spectrum and carbon and hydrogen elemental analysis to determine several important structural parameters, including the fraction of aromatic carbon (f_a) of the sample. The fraction of carbon aromaticity was defined as that fraction of the total number of carbon atoms which are aromatic, $f_a = C_{ar}/C_{tot}$. The normalized intensities of the types of hydrogen were determined from integration of the proton spectrum to calculate the carbon aromaticity using the equation:

$$f_a = \left[(C/H) - (H_\alpha/x) - \frac{(H_\gamma + H_\beta)}{y} \right] / (C/H) \quad (1)$$

where C/H is the atomic ratio of carbon to hydrogen from elemental analysis data; x and y are the average number of hydrogen atoms per α -alkyl group to an aromatic ring and the remaining alkyl groups, respectively; and H_α and $(H_\gamma + H_\beta)$ represent the normalized integrated intensities of the α -alkyl hydrogen atoms and other hydrogen atoms, respectively. From this basic equation can be deduced other key structural parameters, such as the degree of aromatic ring substitution, i.e. that fraction of peripheral aromatic carbon atoms bearing substituent groups, and the atomic H/C ratio for the hypothetical aromatic ring system, which provides an estimate of the average size of the polycondensed aromatic rings.

In subsequent years, numerous researchers applied the Brown-Ladner equation to a wide variety of coal-derived liquids, including coal extracts, autoclave asphaltenes, carbonization oils, solvent-refined coals, coal tar pitches, and coal liquefaction products. However, there were several assumptions which had to be made in the application of the

Brown–Ladner equation, and the results obtained often depended on assumed values for x and y . For most fossil fuels, x and y were assumed to be 2, which was the same as suggesting that the average aliphatic carbon structure in these materials represented a methylene group. There was also the problem with accurate integration of the H_α and $(H_\gamma + H_\beta)$ protons because of severe overlap of the resonance lines. Derivation of the remaining parameters from the Brown–Ladner approach necessitated accurate deconvolution of the phenolic protons from aromatic protons, which was not always possible because of solvent-induced shifts of the hydroxyl resonances. Nevertheless, the approach was used to estimate the chemical structure parameters for many fossil fuels prior to the advent of high-resolution ^{13}C NMR.

The first high-resolution ^{13}C NMR spectrum of liquid products was published as early as 1966 using computer-assisted techniques. However, it was not until the mid-1970s, after the development of Fourier transform methods, that ^{13}C NMR of liquid and soluble materials from coal became routine.⁹ The first studies focused on comparing aromaticity data obtained directly by ^{13}C NMR with those estimated from the Brown–Ladner treatment of the corresponding ^1H NMR spectra. Several laboratories reported generally good agreement; for example, one correlation of ^1H and ^{13}C NMR data for five coals of different rank, coal tar pitches, coal carbonization oils, coal-derived asphaltenes, and products from five different liquefaction processes is presented in Figure 2.¹⁰ For the case of low boiling coal-derived oils, poor agreement was found because these materials tended to have shorter aliphatic chains, and hence the estimate for the ratio of aliphatic hydrogen to carbon (y in the Brown–Ladner equation) should have been greater than 2. Similar arguments were made for highly aromatic pyrolyzate products, in which there were high amounts of methyl substituents.

Later work focused on the assignment of chemical shift values to ^{13}C spectra of coal liquids. Efforts were made not

only to assign chemical shifts to various carbon functional groups in samples, but also to estimate the relative abundances of these groups. Inference was made for a relationship between ^1H and ^{13}C NMR data on the same sample, leading to the idea that complementary information from both techniques could lead to detailed structural characterization of complex, multicomponent fractions of coal liquids. Thereafter, numerous separation methods and other spectroscopic techniques were combined with characterization by ^1H and ^{13}C NMR to provide detailed structural profiles of individual components in complex coal mixtures.

One of the cornerstones of structural analysis methods has been the information provided by NMR, and there have been many practices of presenting the data. Three approaches that have frequently been used are: characterization by the formulation of structural parameters; characterization by the construction of average, or representative, molecular structures; and characterization by functional group analysis.¹¹ The first approach is considered by many to be limited because estimation of numerous parameters often relies on assumptions about molecular structure, and the average parameters calculated are not guaranteed to represent actual structures in fuel liquids. The use of an average structure, or model, to represent the system is flawed by the latter drawback. The advantage of the functional group analysis approach is that, by definition, it is chemical functionalities that govern the overall chemical and physical behavior of these complex molecular systems.

Functional group analysis has been applied in several laboratories to describe coal extracts and soluble reaction products.¹¹ The initial step in the process was to propose a set of functional groups that described the structure of the complex mixture. The concentrations of this selected set of functional groups were subsequently related to experimental data through a sequence of equations, where the effects of known stoichiometry are taken into account. In general, a set of equations can be written:

$$\sum_{j=1}^n A_{ij} |y_j| = b_i \quad (i = 1, \dots, m) \quad (2)$$

where y_j ($j = 1, \dots, n$) represents the unknown functional group concentrations, b_i ($i = 1, \dots, m$) represents quantities from experimental data, and A_{ij} represents the stoichiometric coefficients. The summation defined a range of possible solutions and a best fit was selected computationally through a minimization procedure by assuming that the distribution of atomic species among the functional groups is equally probable.

These methods have been tested on known mixtures and were subsequently used to characterize complex coal liquids. Utilizing data from NMR and elemental analysis gave fair estimates of molecular composition; incorporating data from mass spectrometry improved the results considerably. Characterization of separated fractions of coal asphaltenes derived from solvent-refined coal heavy distillate and supercritical gas extracts from two different coals provided information on the hydroaromatic content, distribution of heteroatomic functional groups, and nature of the polycondensed aromatic rings structures. In addition, these same methods have been used to reliably predict the thermophysical properties of liquid fuels,

Figure 2 Comparison of proton (f'_a) and carbon (f_a) aromaticities for materials derived from coal; H-coal, solvent-refined coals, COED, and Synthoil are liquefaction processes

by utilizing group additivity principles and the idea of continuous thermodynamics.

Numerous studies have centered on the use of conventional solution state NMR techniques to study the heteroatomic functional groups in coal-derived liquids, principally those containing oxygen, nitrogen and sulfur.¹² Regions within the ^{13}C NMR spectra of coal asphaltenes and coal-derived oils were examined and assigned to carbonyl groups, aromatic ethers and phenols, aliphatic ether groups, and nitrogen groups. Other investigations have employed derivatization methods to specifically 'tag' functional groups in combination with NMR analysis. Several approaches have been attempted. These include: either acetylation or reductive alkylation followed by ^{13}C NMR; trimethylsilylation with analysis by ^1H , ^{13}C and ^{29}Si NMR (see Figure 3); hexafluoroacetone adduction which can be analyzed by ^{19}F NMR; and phosphorylation followed by ^{31}P NMR. Direct analysis by ^{17}O NMR has facilitated examination of some fractions of coal liquids, leading to the identification of oxygen functional groups on the basis of their chemical shifts: for instance, alcohols, phenols and ethers; furans and carboxylic acids; esters; and ketones and aldehydes.

Given the complicated nature of the ^{13}C spectra of coal-derived liquids, several multipulse techniques based on the spin echo method were developed which allowed the selective examination of different carbon types.^{11,12} The gated spin echo (GASPE) or partially coupled spin echo (PCSE) pulse sequences were used to differentiate between aliphatic quaternary C and CH_2 , as one phase-related spin group, and CH and CH_3 as the other. The same techniques were also applied to obtain edited aromatic carbon spectra, for which the distinction between quaternary and tertiary aromatic carbon atoms could readily be made. The spin echo broadband off-resonance decoupling (SEBBORD) technique was used to differentiate further between quaternary and CH resonances on the basis of broadening of the CH resonances. Later, with the development of polarization transfer pulse methods, the use of either INEPT or DEPT sequences allowed separation of the entire carbon spectrum, into quaternary C, CH, CH_2 and CH_3

Figure 3 A typical ^{29}Si NMR spectrum of a coal liquid derivatized with trimethylsilyl chloride

resonances. Utilization of two-dimensional J -resolved and ^1H - ^{13}C COSY experiments on coal liquids, however, has met with limited success.

2.1.2 Solid State NMR

The earliest report on the use of broadband ^1H NMR in coal research was published in 1955 by Newman et al.¹³ However, apart from demonstrating that the NMR experiment was feasible on such materials, little chemical information was gleaned from this original work. It was more than 20 years later, in 1976, when the first solid state ^{13}C NMR spectra appeared in the literature,¹⁴ utilizing then recently developed CP methods for sensitivity enhancement together with strong proton decoupling.¹⁵ These initial ^{13}C spectra, recorded for four coal samples of different rank, are shown in Figure 4. It was the first time that coal structure was determined by a direct method for whole coals in their native state. Less than a year later, MAS with respect to the static magnetic field was used in combination with CP and proton decoupling to produce the first high-resolution solid ^{13}C CP MAS spectra of coal.¹⁶ This constituted a major breakthrough in the field; removing broadening effects arising from both CSA and ^1H - ^{13}C dipolar interactions produced isotropic resonance lines and facilitated the analysis of different carbon functional groups in coals. Also during 1977, MAS was combined with multiple pulse methods to produce the first high-resolution ^1H CRAMP spectra of whole coal samples.¹⁷ The technique facilitated analysis of aromatic and aliphatic proton distributions of coals in their native state.

Applications of solid ^{13}C CP MAS and ^1H CRAMP spectroscopy in coal structure determination have been reviewed extensively.^{12,18-22} Early ^{13}C CP spectra of coals (see Figure 4) exhibited two broad, overlapping resonance bands

Figure 4 CP ^{13}C NMR spectra of coals of increasing rank

estimate the fraction of substituted and bridgehead aromatic carbon atoms (f_{s+b}), and the number of quaternary aliphatic carbon atoms in these systems. Attempts to estimate the average cluster size of the aromatic rings from these data has had the caveat that it has been impossible to assign aromatic substituted and bridgehead carbon atoms with confidence because of severe overlap of the resonances. Nevertheless, interrupted decoupling solid state NMR has provided valuable insight into the nature of coal as a macromolecular material, and the technique has been used to explain some of the chemistry occurring upon its treatment under a variety of conditions.

Interrupted decoupling has also been employed with detection by CRAMPS to enhance the resolution of solid state proton spectra of carbonaceous materials.²² Analogous to the carbon version of the experiment in CP MAS spectroscopy, a dephasing period is inserted between the initial $\pi/2$ pulse that places the proton magnetization in the transverse plane and initiation of the multipulse decoupling sequence used for detection. The technique has been used on pyridine-sorbed coals and has provided selectivity of protons on the basis of molecular mobility.²²

Mathematical manipulation has been employed to enhance the resolution of solid NMR coal spectra.¹⁸ The several methods that have been implemented include: (1) convolution difference spectroscopy, which uses a filtering function composed of two exponentials and an adjustable weighting constant; (2) Gaussian multiplication, which has been used to improve resolution on the basis of lineshape modification; and (3) a variety of curve and Fourier deconvolution methods, for which the usual practice has been to fit mathematically a broad band of unresolved resonances to a series of peaks that are varied according to frequency position, lineshape, linewidth, and intensity.

Resolution enhancement in these systems has also been achieved based on carbon and proton relaxation time differences in CP MAS experiments.¹² Differentiation of carbon atoms in coals has been accomplished on the basis of differences in ^1H – ^{13}C polarization transfer rates R_{CH} , proton rotating frame spin–lattice relaxation rates $R_{1\rho}^{\text{H}}$, and carbon spin–lattice relaxation rates R_1^{C} .

Chemical derivatization techniques in conjunction with solid state ^{13}C NMR have been used to highlight the reactive oxygen functional groups, such as phenols, aliphatic alcohols and carboxylic acids. Acetylation¹² was employed to target specifically hydroxyl groups in coals and could be monitored by the introduction of additional carbonyl and methyl resonances in the solid reaction products. Comparing integrated signal intensities of the introduced acetyl resonances with those of native C–O gave estimates on the amounts of hydroxyl versus ether groups. The combined use of selective alkylation with ^{13}C -enriched methyl iodide and solid state ^{13}C NMR has also facilitated the assignment of methyl carboxylates, unhindered aryl methyl ethers, and hindered aryl methyl ethers in coals^{25,26} and isolated coal macerals.²⁷

Solid state NMR spectroscopy has seen limited applications to the study of mineral phases in coals. The first application focused on the use of ^{29}Si and ^{27}Al NMR to characterize mineral concentrates obtained by low temperature ashing of coals in order to obtain information on their mineralogy.²⁸ Silicon spectra allowed the identification of silicate resonances from quartz and clays, while aluminum spectra provided

information on the tetrahedral and octahedral coordination sites which allowed discrimination between kaolinite and illite clays that were present in the concentrates. A subsequent study²⁹ on mineral residues obtained from coal flash pyrolysis indicated that ^{29}Si and ^{27}Al spectra were broad because of the presence of paramagnetic species; however, the spectra were sufficiently resolved to detect the thermal transformation of kaolinite to quartz and mullite with increasing pyrolysis temperature. Characterization of the layer silicate minerals in the suite of Argonne Premium coals was carried out by using sink-float techniques to isolate mineral concentrates in combination with ^{29}Si and ^{27}Al NMR.³⁰ CP MAS and VAS techniques were employed to distinguish between the various clay minerals; quartz, kaolinite and smectite clays could readily be identified. Tetrahedral/octahedral aluminum ratios were determined for the coals, and the observation of increasing tetrahedral aluminum content with coal rank indicated there was a parallel between the diagenesis of the organic and inorganic matter in the coals.

2.1.3 Determination of Physical Structure

Solid state NMR spectroscopy has been applied extensively to the study of complex molecular dynamics in synthetic polymers. However, such investigations of coals have been limited. Work in this area has been hampered by the complex nature of coal. Interpretation of nuclear relaxation, which underlies the study of molecular motion, is complicated by the existence of discrete heterogeneous domains in coals and by relatively large quantities of paramagnetic centers which are present either in the form of paramagnetic inorganic ions or as organic free radicals.

To date, an overwhelming majority of papers dealing with relaxation measurements on coals has focused on the study of ^1H NMR spin–lattice relaxation times both in laboratory (T_1) and rotating ($T_{1\rho}$) reference frames. Early ^1H NMR measurements^{31–34} indicated that proton T_1 times in coals can either display single exponential or nonexponential relaxation behavior. The observation by Yokono et al.³³ that T_1^{H} varied linearly with the square root of resonance frequency for several bituminous coals was consistent with diffusion-limited relaxation to paramagnetic centers. Several laboratories^{34–37} later demonstrated similar behavior for a wide variety of evacuated coal samples. The work indicated that spin–lattice relaxation may be a fundamental property of coals themselves, and be independent of either their oxygen or moisture content. In two specific papers,^{37,38} the authors independently proposed that proton relaxation in bituminous coals was influenced by differences in molecular mobilities rather than by the relative concentrations of paramagnetic species.

A difficulty with the interpretation of spin–lattice relaxation of abundant proton spins in coals rests with the development of an experimental strategy to separate contributions from molecular mobility from spin diffusion of the magnetization to paramagnetic centers within different phase (maceral) boundaries. Three thorough investigations of ^1H NMR spin–lattice relaxation in coals^{39–41} have attempted to address this issue. The authors independently concluded that simple correlations of proton relaxation with other coal parameters was not easily realized. The presence of residual amounts of molecular oxygen in evacuated samples and the effects of different concentrations of unpaired electrons within different domains in

coals were thought to have a profound, yet undeterminable, influence on the relaxation times. Others⁴² have reported proton relaxation data for eight Argonne Premium coals and three oxidized coals and have shown that oxidized samples have shorter T_1^H values. Finally, in careful T_1^H and ESR studies of Argonne coals, various chemical treatments established that the important proton relaxation mechanism in lignite and subbituminous coals was due to the presence of paramagnetic mineral ions, whereas that in the higher rank coals is due to organic free radicals.⁴³

The problems were not confined to measurements of T_1^H . An early paper⁴⁴ reported proton $T_{1\rho}$ values for a pitch and three Canadian coals and had emphasized the effects of paramagnetic species, including oxygen, on the experimental results. Other studies indicated a general trend, but lack of any definitive correlation, between $T_{1\rho}^H$ values and radical concentrations for a series of 'more homogeneous' maceral concentrates.⁴⁵ It was concluded that the $T_{1\rho}^H$ values for macerals are clearly complicated by having two competing mechanisms for relaxation, i.e. molecular motion and heterogeneous spin diffusion to paramagnetic centers. Without knowledge of the relative contributions of each to the overall relaxation times in the individual samples, any meaningful interpretation of the data was impossible. In the case of a homogeneous resinite sample doped with increasing amounts of a stable organic radical, however, an excellent correlation of $T_{1\rho}^H$ with radical concentration could be established.

In contrast with proton relaxation, relatively little work has been done on the measurement of ^{13}C relaxation times in coals. Carbon-13 spin-lattice relaxation measurements have been carried out on a bituminous coal from the Powhatan No. 5 mine.^{46,47} It was established that aromatic resonances in this sample decayed with a single time constant, while the aliphatic resonances could be separated into two distinct regions having markedly different time constants for decay. Differences observed in the T_1^C values for different spectral regions were interpreted in terms of molecular motion, although the contribution of free radicals to spin relaxation were acknowledged as being important as well. Other researchers⁴⁸ investigated the effect of static field strength on the T_1^C relaxation parameters of five Argonne Premium coals and five Canadian coals, and correlated the relaxation times with various coal properties.

In a recent study,⁴⁹ eight Argonne Premium coals and three weathered Argonne coal samples were investigated and the proton and carbon spin-lattice relaxation times were reported for aromatic and aliphatic carbon atoms. In general, the proton and carbon spin-lattice relaxation data could be evaluated as the sum of two exponential decays. The longer components of carbon relaxation times in the laboratory and rotating reference frames were found to vary in a systematic way with coal rank, and the trends were explained in terms of motional properties of the coals and the presence of paramagnetic species. Marked increases in the carbon $T_{1\rho}$ values observed between pristine and weathered coals were interpreted to indicate a decrease in molecular mobility resulting from increased cross-linking as a result of oxidation.

2.1.4 Advanced Characterization Techniques

Several NMR methods have appeared in the recent literature on coal which deserve particular attention. They often

incorporate special pulse sequences for solids aimed at sensitivity enhancement, spectral simplification or resolution enhancement, and multidimensional NMR spectroscopy and imaging.

The first two-dimensional ^1H - ^{13}C COSY experiment on a coal was demonstrated in the mid-1980s.⁵⁰ By dispersing the carbon and proton spectral information over two dimensions (see Figure 6), the proton resonances became separated such that the aromatic, methylene and methyl protons could be resolved and their abundances estimated. Similar methods were applied to the analysis of the proton content of macerals.⁵¹ Overlapping carbon functional groups have been estimated from two-dimensional dipolar shift (DIPSHIFT) techniques.⁵² In the latter experiment, isotropic chemical shifts were plotted on a frequency axis facing dipolar shift sideband spectra on a second axis. Multiplicity of individual sideband patterns in the aliphatic region were then used to assign resonances in the isotropic spectrum on the basis of the number of protons attached to each carbon atom.

Dynamic nuclear polarization has been used with some success for the analysis of a wide range of coals of varying rank.⁵³ By polarizing carbon spins via the electron spins directly, or by CP techniques through the protons, large signal enhancements have been possible.⁵⁴ The technique has allowed the analysis of coals in short measuring times; however, because polarization is transferred from electron spins that reside predominantly within aromatic structures, the technique has generally overestimated the carbon aromaticity values in these systems.

Determination of the principal values of carbon CSA in anthracite coals and fusinite macerals through lineshape analysis has led to the quantitative analysis of the different carbon bonding types in these systems.⁵⁵ Using powder pattern lineshapes, three different bands due to aromatic condensed bridgehead and inner carbon atoms, and substituted carbon atoms were readily distinguished. The mole fractions of the condensed aromatic carbon atoms were then used to estimate the average cluster size of the polycondensed aromatic hydrocarbons in the coals. Later, VAS experiments were

Figure 6 (a) The heteronuclear shift correlation spectra of Illinois No. 6 coal with three fully resolved contours (1, 4, and 5) and two partially resolved contours (2 and 3) observed. (b) Proton spectra from slices at 1, 4, and 5

carried out in conjunction with powder pattern analysis in order to unscramble overlapping shielding tensors in coals and macerals.⁵⁶ A review of possible methods for obtaining carbon shielding tensor information on coals has recently appeared;⁵⁷ methods for separating individual CSA patterns in complex spectra include VAS, slow MAS, chemical shift correlation spectroscopy, magic angle hopping (MAH), stop-and-go (STAG) methods, DAS, and MAS with synchronized pulsing.

The first direct magnetic resonance imaging (MRI) experiment on solid coal and maceral specimens appeared in 1989.⁵⁸ These initial studies (see Figure 7) demonstrated the potential of MRI spatially to map proton distributions in whole coals. Individual macerals within the coals were readily distinguished by image contrast based on differences in proton density or spin–lattice relaxation. A subsequent MRI investigation focused on elucidating changes in the physical structure and on determining solvent accessibility parameters in solvent swollen coals.⁵⁹ Other researchers have utilized MRI to determine the distribution of water in coalified woods and low-rank coals.⁶⁰ Correlation of proton spin distributions determined by MRI with the void spaces from other techniques allowed analysis of porosity and permeability in the specimens. Transient MRI studies of solvent penetration into solid coal and polymer specimens has led to a detailed understanding of transport phenomena for systems in which the glass transition is induced by solvent; the data have led to the development of a new model for anomalous transport behavior in coals and other glassy polymer systems.⁶¹

2.2 Conversion Processes

The combined use of ^1H and ^{13}C NMR has been employed to examine the chemical behavior of coal, in reactions such as oxidation which may be undesirable, in thermolysis and pyrolysis reactions, and in upgrading reactions for its conversion into clean, high quality liquid fuels, and chemical feedstocks.⁶² Studies in the liquid state have provided information on the liquefied products, while solid state NMR

has been used to characterize the original coal material as well as the chars and cokes produced in these reactions.

Several researchers have focused their efforts on characterization of coal oxidation. Early proton relaxation time measurements have been used to explore oxidation of cokes in air at elevated temperatures. The data were compared with changes in the optical texture of the coke, and a correlation between the appearance of an isotropic phase and the T_1 minimum was found. T_2 experiments indicated that the mobile phase becomes more rigid, which was interpreted to reflect an increase in the degree of cross-linking. Structural studies carried out with ^{13}C CP MAS showed that a decrease in aromaticity accompanied oxidation of coals in air at elevated temperatures. Independent studies indicated that oxidation caused a loss of specific functional groups in the aliphatic region; an increase in carbon aromaticity was observed, contradicting previous results. Conflicting evidence was also reported in the literature concerning either the appearance or disappearance of certain aromatic structures, with specific reference to phenolic structures.

Other researchers have focused on elucidating structural changes after low-temperature oxidation, or weathering, of coals of different rank. Little change in the aromatic carbon content was noticed; however, the amount of the aliphatic CH_2 was found to decrease significantly after weathering. Dipolar dephasing studies were also in conflict with earlier elevated temperature experiments. Consequently, the entire body of evidence in the NMR literature has been inconclusive regarding specific structural changes that accompany oxidation. Investigations^{49,63} involving oxidation or prolonged weathering of Argonne Premium coals later established that changes in free radical content significantly affect pertinent relaxation times in CP MAS and dipolar dephasing experiments. These relaxation effects may in fact account for the discrepancies found in previous comparisons of NMR data between native and oxidized coal samples, ultimately leading to conflicting results on different coals.

The use of NMR for characterizing coal liquids derived from liquefaction processes began as early as 1975.⁶⁴ Proton NMR, and in several instances ^{13}C NMR methods, including CP and CP MAS, have been applied to study coal liquefaction under different conditions to produce solvent refined coals, H-coals and Synthoil products.^{10–12,65,66} NMR has played an important role in coal liquefaction research because it has been the only method able to characterize the complement of materials involved in the process, including the original coal feedstocks, liquid products, solid residues and products, catalyst materials, and solvent systems. The functional group analysis approach has been widely used to examine the structural changes in coal liquefaction and has led to the following general conclusions concerning the overall process in tetralin: (1) hydroaromatic structures are partially or completely dehydrogenated, while others are cleaved during the reactions; (2) alkyl groups in the products result from cleavage of the hydroaromatic ring structures; and (3) aromatic structures are formed via dehydrogenation reactions.

With the advent of ^{13}C CP MAS spectroscopy, not only liquid products but also the solid residues from liquefaction became amenable to analysis by NMR. The chars formed after prolonged reaction times at higher temperatures tended to have extremely high aromatic carbon content, (f_a up to 0.96). In general, it was found that the aliphatic content of

Figure 7 Two-dimensional xy images of resinite (left) and vitrinite (right) macerals using rotational gradients and MREV-8 back-projection reconstruction protocol with 90 projections about 180° , and 512 averages per projection. The recycle delays used in A–D were 235, 585, 1085, and 1585 ms, respectively

the chars decreased with increasing hydrogenation time while the composition of the liquid products remained relatively constant. Also observed was a marked decrease in the number of polar functional groups. The general conclusions drawn from the NMR results suggested a mechanism involving the decomposition of hydroaromatic structures, whereby under higher temperature reaction conditions an increasing proportion of aliphatic structures was converted into aromatic material and/or gaseous products. Furthermore, the increase in the polycyclic aromatic content meant that hydroaromatic systems were decomposing via retrogressive condensation reactions. Most recently, coal liquefaction residues were characterized by solid state CP MAS techniques.⁶⁷

Other researchers⁶² have focused on the use of CP MAS to study coking deposition on coal liquefaction catalysts, which was thought to be one of the principal causes of catalyst deactivation. Several studies⁶² have compared liquefaction behavior in the presence of different catalysts or with no catalyst at all, and have compiled results on the reaction yields and quality of liquid products. Both ¹³C and ¹H NMR have been used to monitor the hydrogen donor solvent employed in liquefaction. The results demonstrated that loss of hydrogen in the solvent occurs primarily via aromatization of hydroaromatic structures. By estimating the concentration of donatable hydrogen of the liquefaction solvent through chemical shift assignments, hydrogen donor values of various solvents were independently derived.

Labeling studies employing deuterated tetralin have been used with great success to study hydrogen transfer processes during liquefaction and to follow the incorporation of deuterium into liquid products.⁶² A combination of ¹H, ²H, and ¹³C NMR and separation methods such as gel permeation chromatography was employed to study the evolution of coal liquefaction products in *d*₄-tetralin.⁶⁸ Later on GASPE, INEPT, and two-dimensional *J*-resolved NMR were used to obtain more detailed structural information on exchange mechanisms of hydrogen and deuterium.^{11,69,70} The majority of studies on a wide variety of coals and catalyst systems led to a common conclusion: the distribution of deuterium in liquefaction products was found to be reasonably representative of the fate of hydrogen incorporation into coal tars. While there was some total scrambling of hydrogen, for the most part hydrogen was incorporated into aromatic residues and at α - and β -carbon atoms preferentially attached to aromatic structures.

The ability of NMR methods to provide reasonably quantitative information on the distribution of hydrogen in both the starting coals, liquid and solid reaction products, and solvents has made it possible to account for the total hydrogen consumption in liquefaction.⁶² A mass balance equation for the total consumption of hydrogen in liquefaction has been derived:

$$\Delta H = \Delta f_a + \Delta(C - C) + \Delta NOS \quad (3)$$

where ΔH is the net change in hydrogen between the original coal and all liquefaction products, Δf_a is the corresponding change in total aromaticity, $\Delta(C - C)$ is the total number of carbon-carbon bonds ruptured via hydrogenolysis, and ΔNOS is the composite loss of nitrogen, oxygen, and sulfur atoms. The NMR data combined with information from elemental analysis were used to estimate the fate of total hydrogen utilized in hydrogenation processes leading to reduction,

carbon-carbon bond-breaking reactions which generate either light gases or liquid products, and for removal of heteroatoms. The NMR approach of using the concept of total aromaticity as a means to assess the mass balance of consumed hydrogen has been an important step in evaluating the performance of liquefaction processes and has offered some of the best insights into coal liquefaction chemistry to date.

Numerous investigations have also been concerned with developing an understanding of the fundamental chemical processes involved during coal pyrolysis and carbonization.⁶² NMR has been used to study the response of coals to heating, by comparing data on solid and liquid products with the data obtained on the original solid coals. Researchers have developed comprehensive models based on the changes in functional groups during pyrolysis. Specific information on changes in aromaticity, degree of substitution on aromatic structures, types of aliphatic functional groups, and aromatic ring condensation have been compiled by both ¹³C NMR, and ¹H NMR using the approach of Brown and Ladner, together with compiled data on the yields of aromatic hydrogen and carbon as a function of temperature during pyrolysis. General conclusions have been summarized on the basis of the results: (1) only the weakest coal bonds fragmented at temperatures below 600 °C; (2) maximum yields were obtained at temperatures of 600–700 °C with little change observed in the aromatic structures and marked changes in the aliphatic components, suggesting that significant decomposition in the aliphatic substituents had occurred; and (3) at temperatures above 700 °C the less condensed aromatic structures began to decompose into gaseous products.

The nature of flash pyrolysis tars produced from a wide variety of coals throughout the world has been investigated by NMR techniques in several laboratories.⁶² In general, it was found that larger polycyclic aromatic ring structures were produced at higher pyrolysis temperatures. However, results compiled from a survey of many pyrolysis experiments suggest that the nature of the coal and the method of pyrolysis rather than the final pyrolysis temperature were most important in determining tar structure. Alkenes in the tars were correlated with the decomposition of polymethylene chains, while ¹³C NMR suggested that a large proportion of the alkyl carbon atoms were part of long-chain alkyl groups. NMR analysis of chars produced in variable temperature flash pyrolysis experiments showed that the aliphatic peak decreased with increasing pyrolysis temperature, while the aromatic band remained unchanged, suggesting that the aromatic content in the char was relatively constant. Furthermore, NMR studies demonstrated that the carbon aromaticity of the original coal, (f_a), or the amount of methylene structures present in the tars were linearly correlated with tar yields in coals ranging from bituminous to semianthracite; lignite tar yields, however, did not correlate well. Based on these results, it was concluded that aliphatic carbon atoms in coals, in particular the methylene groups, were essential to the production of pyrolysis tars. Later studies employing NMR considered correlating pyrolysis yields with the loss of specific regions of chemical shift within the aliphatic and aromatic resonance bands. The production of gases was consistent with decreases in the CH₂ resonance at 30 ppm. On the other hand, high tar yields correlated well with the loss of the remaining aliphatic groups in the region 13–47 ppm, i.e. consistent with the loss of hydroaromatic

structures in the coals. In addition, coal aromaticities correlated well with char production.

In general, the majority of coal processing technologies involve heating, and it is in this area that NMR has played a unique role in understanding the physical behavior of coal at the elevated temperatures typically employed in hydroliquefaction and other catalytic upgrading processes. Wideline ^1H NMR has been used to study changes in the molecular mobility or viscosity of coals during heating to temperatures as high as 875 K.^{62,71,72} Early studies measured changes in $\Delta H_{1/2}$. However, later on the use of second moment (M_2) analysis of the solid echo signal led to a more accurate representation of average molecular mobility. Variations in M_2 with temperature were consistent with a depolymerization of the coal structure followed by recondensation. The concurrence of temperatures for M_2 minima and bulk fluidity from Giesler plastometry suggested that there was a significant molecular basis to the thermoplasticity of coal. In general, a strong correlation was found between hydrogen content, and perhaps high sulfur content, with coal fusibility.

2.3 The Quest for Quantitation

^1H and ^{13}C NMR spectroscopy have been applied with great utility to the analysis of hydrogen and carbon functional group distributions in a wide variety of liquid and solid fuels and their reaction products. The increasingly important role over the past three decades of NMR as a characterization tool for fuels has led to a significant advance in our understanding of their structure, origin, and evolution. The enormous impact that NMR has made in the area of fuel research has been a direct consequence of its utility as a quantitative tool. In principle, NMR of spin- $\frac{1}{2}$ nuclei is unique as a spectroscopic method in that the transition probabilities of each and every isochromat in the absorption spectrum is the same, or unity. Notwithstanding this unique capability, from the outset concerns about the quantitative reliability of ^{13}C NMR spectroscopy has placed the general utility of the method in question. Carbon-13 NMR in liquids was perceived in this way until the mid-1970s, when its usefulness as an analytical technique was demonstrated by the judicious implementation of the proper pulse techniques and recycle delay times, sometimes with the aid of relaxation reagents to shorten spin-lattice relaxation times and to suppress the nuclear Overhauser effect. For ^{13}C analysis of solid coal samples, the issues regarding quantitation were not resolved until the late 1980s because of the enormous complexities involved.

With the advent of ^1H decoupling,¹⁵ CP¹⁵ and MAS,⁷³ which have made it possible to obtain high-resolution ^{13}C NMR spectra in solids in a relatively short measuring time, CP MAS techniques have been applied extensively in coal research.^{12,14,18,42,74–78} In fact, ^{13}C CP MAS NMR has become one of the most widely used methods for investigating coal. However, there has been growing concern during the past decade about the quantitative reliability of CP MAS spectroscopy for coal analyses. In the very first ^{13}C CP NMR study of coal,¹⁴ it was estimated that only about 50% of the total carbon spins could be detected via this technique. Since then the issue of quantitation in NMR analyses of coal and related materials has been a topic of much

debate.^{14,44,45,47,75,79–85} Although the quantity of observable carbon atoms for coals and their macerals have been shown to vary widely, the general consensus was that, for reasons which can be related to both specific coal properties and the applied NMR techniques, a substantial fraction of the carbon atoms was not observed.

It was known that coal is one of the most complex carbonaceous materials known. It was by nature an extremely heterogeneous solid composed of a number of distinct organic phases termed macerals, and to a lesser extent, of an inorganic mineral phase. Each maceral and mineral phase exhibited a unique set of physical and chemical properties that contributed to the overall behavior of coal. The macerals typically ranged in size from micrometers upwards, and pure bands were commonly found in coal seams up to meters in thickness. Consequently, maceral dimensions were sufficiently large to expect that nuclear spin diffusion across maceral boundaries would be incomplete on the NMR timescale, typically on the order of 1000–2000 pm and 10^4 to 2×10^4 pm in the limits of proton relaxation in the rotating frame and laboratory frame, respectively. This meant that nuclei within different maceral phases acted as isolated spin reservoirs with very different magnetic properties.

There were additional factors to consider as well. Individual macerals were in many instances intimately associated with inorganic minerals, some of which may contain paramagnetic ions. Moreover, the macerals contained different concentrations of organic free radicals, causing relaxation time differences that would ultimately govern the evolution of magnetization within these isolated domains. The presence of paramagnetic centers raised the possibility that significant portions of the carbons were sufficiently broadened or shifted outside the spectral range to render them invisible in the NMR experiment. Moreover, variations in free-radical content among these isolated phases was shown to lead to serious distortions in the carbon signal measured for the entire coal sample.

Thus, complexities in the organic, inorganic, and physical structures of coal limited the quantitative reliability of solid ^{13}C NMR measurements. The inherent limitations associated with measuring a complex solid such as coal were unavoidable. However, a fundamental understanding of these complexities was necessary in order to establish confidence limits for the measurements so that meaningful parameters could be obtained from the data.

A comprehensive review on the subject of quantitation in solid NMR analysis of coals has recently appeared.⁸⁶ In that review, several factors limiting quantitation in both single pulse and cross polarization experiments were discussed along with possible remedies. Important aspects to the problem of quantitation included in that discussion were: the nature of the unpaired electron spin interactions; interference between molecular motions and the proton decoupling field; insufficient MAS rotation; interference between molecular motions and MAS; consequences of long spin-lattice relaxation times; dependence of the Hartmann–Hahn matching condition; modulation of C–H coupling due to MAS; and complexities involving CP spin dynamics.

Finally, resolution of the issues concerning the quantitative reliability of solid ^{13}C measurements was made possible by the establishment of a standard, homogeneous suite of coal samples. As in other disciplines of fuel science, the complex nature of carbonaceous fuels together with the diversity of

samples chosen for study has made comparisons between published results difficult. With the inception of the Argonne Premium Coal Sample Program,⁸⁷ NMR results on a common suite of pristine coal samples spanning a diverse rank range could be compared.⁸⁸ Thus, valid comparisons between data measured using different experimental techniques and under a variety of different experimental conditions had become feasible for the first time.

A comparison has been made of data obtained from experiments which were carried out at static field strengths ranging from 1.4 to 9.4 T (corresponding to carbon resonant frequencies of 15–100 MHz) and using a variety of methods, including CP MAS, single pulse excitation (SPE) with MAS, MAS with TOSS, and DNP CP without MAS. Carbon aromaticities were determined from CP experiments employing contact times generally between 1–2 ms and, in certain instances, by mathematically fitting signal intensities derived from variable contact-time experiments. Proton decoupling field strengths employed were typically 40–82 kHz; MAS frequencies varied from 3 to 13 kHz. Recycle delay times ranged from 1–3 s in CP experiments to 60 s in SPE experiments.

For bituminous coals, mean carbon aromaticity values that were determined for three data sets (CP MAS, CP MAS at 2.3 T, and SPE) were found to be the same within the limits of the standard deviations. The results indicated that the variability in carbon aromaticities reported by different laboratories for the coals was greater than the differences observed between experimental techniques, i.e. CP and SPE experiments. However, the mean values from SPE experiments always tended to be on the high end of the range of CP values.

Differences in mean carbon aromaticity values for CP and SPE experiments were found to be significant for the two low-rank sub-bituminous and lignite coal samples. Their mean SPE carbon aromaticities were clearly higher by approximately 10% and 20%, respectively. The differences were accounted for by complications arising from paramagnetic transition metal ions intimately associated with the coal organic phase. The presence of paramagnetic metal ions in these coals was shown adversely to affect their spin–lattice relaxation properties,⁴⁸ and these factors were invoked to explain lower derived CP MAS aromaticity values resulting from reduced CP efficiencies.

Comparing mean CP and SPE aromaticity values for Argonne coals with aromaticities obtained by other pulse techniques showed the expected trends. While carbon aromaticities obtained using the TOSS pulse sequence in one laboratory were in reasonable agreement with the mean, those reported by other laboratories turned out to be significantly lower than mean CP or SPE aromaticity values. The disparity of the TOSS results illustrated the severe demands that are placed on proper implementation of the TOSS pulse sequence for quantitative analysis. On the other hand, aromaticity values obtained from DNP CP experiments tended to be high, which was entirely consistent with signal enhancement via electron–nuclear polarization from free radical centers that reside within aromatic coal structures.

The principal conclusion gleaned from the interlaboratory study was that SPE methods generally gave the most reliable results. Proper sample handling techniques to prevent oxidation or weathering of samples was also thought to be an important factor in the analysis of coals.

2.4 Origin of Coal and its Evolution

From the beginning of its deposition at the surface of the Earth and throughout its burial, sedimentary organic plant debris underwent progressive changes in composition and structure; when the process involved has related specifically to the metamorphosis of coal, it has been generally referred to as ‘coalification’.⁸⁹ The nature of metamorphic processes of coal has changed significantly at different stages of its evolution. At the earliest stages, coalification was dominated by microbial reactions and physical processes such as maceration and compaction. Later stages of coalification were governed predominantly by abiogenic chemical reactions such as dehydration, dehydrogenation, and aromatization, as well as polymerization and depolymerization reactions. The final stages involved graphitization processes, leading eventually to the formation of anthracite.

During the past three decades, there have been numerous investigations concerned with elucidating the important chemical processes responsible for the transformation of plant biopolymers into the specific organic macerals that compose coals.⁸⁹ During the 1980s, numerous studies employing NMR techniques sought to uncover the chemistry involved in the transformation of woody tissue, obtained from both natural and synthetic sources, into the maceral vitrinite. Often, NMR studies were carried out in parallel with analysis by mass spectrometry. The structural evolution of vitrinite was studied through detailed characterization of naturally occurring coalified log specimens which spanned the entire coalification range.^{90–94} In independent studies, laboratory simulated coalification experiments were carried out on lignin samples isolated from modern wood, in the presence of clay catalysts at relatively low temperatures (150 °C).⁹⁵ Subsequent simulated coalification investigations^{96,97} focused on solid state ¹³C and ¹H NMR analyses of synthetically prepared ¹³C-labeled lignins⁹⁸ and model compounds to monitor abiogenic evolution pathways. The remarkable parallels found between solid state ¹³C spectra of artificial coals and naturally occurring coalified specimens of similar maturation level laid the framework which revolutionized modern thinking on the process of coalification.

Previous views of coalification held that in early stages of diagenesis plant biopolymers (predominantly lignin) were degraded and depolymerized through microbial transformation into low molecular weight humic substances, and these materials subsequently repolymerized to form the macromolecular building blocks that became coals. The bulk of recent results from studies by NMR has not validated this paradigm of coalification. Rather, evidence has mounted indicating that coalification of woody tissue proceeded primarily by selective preservation of lignin structures, as biochemical processes removed carbohydrates preferentially, followed by a subtle thermal alteration of lignin directly into the macromolecules found in coal. There was little evidence to suggest that any major disruption in lignin structure had taken place; consequently, humic acids were no longer considered major intermediates in the formation of coal.

From investigations of coalification of both natural and synthesized precursors, evolutionary changes in the chemical structure of vitrinite were clearly delineated throughout the principal stages of coalification, and detailed mechanisms leading to its transformation could be sketched. It was shown that

initial biochemical stages of coalification involved the complete loss of hemicellulose structures, as well as a significant loss in cellulose from woody tissue, with minimal alteration of lignin. Later diagenetic stages leading to the formation of lignite coals resulted in complete loss of all the carbohydrates and some modification of lignin structure. The changes observed were predominantly rearrangement reactions of the aryl-ether bonds that formed linkages between the 3-methoxyphenol subunits; concomitant with these processes was demethylation of methoxyl groups followed by concerted methylation of the aromatic rings to produce methylcatechol structures. The final stages involving transformation into bituminous coals were characterized by reactions that resulted in complete demethylation of the aromatic methoxyl groups and subsequent reductive elimination of the 3-hydroxyl groups to form predominantly phenol-like building blocks. Progression to the higher rank bituminous coals was distinguished by the continued loss of oxygen functionalities along with ring condensation reactions leading to the formation of increased amounts of polycyclic aromatic structures.

3 APPLICATIONS TO SHALE OIL RESEARCH

Oil shales⁹⁹ are fine-grained sedimentary rocks that contain complex organic polymers ranging in molecular weight. There are two fractions of organic matter present: bitumen constitutes the fraction that is soluble in common organic solvents and kerogen constitutes the major portion of organic matter that is insoluble in organic solvents. The organic kerogen fraction is thought to be a cross-linked, three-dimensional macromolecular network of high molecular weight. Oil shale deposits were formed throughout geological time by the slow deposition of organic and inorganic residues in ancient lakes and inland seas. As the bodies of water stagnated and evaporated to dryness, the organic and inorganic matter compacted into sedimentary rock. The structure and composition of the inorganic and organic kerogen components of oil shale vary significantly with the location and the history of the sedimentary basin. If the organic portion originated from a land-based plant source, the kerogen fractions are similar in composition to coal, tend to be highly aromatic materials with hydrogen contents of about 5 wt%, and yield little oil on pyrolysis. On the other hand, kerogen fractions derived from marine aquatic sources tend to have high hydrogen contents ranging from 10 to 12 wt% and are good sources of oil.

Because oil shale kerogen was completely insoluble in common solvents, direct structural and compositional data were difficult to obtain without first performing time-consuming isolation and preparation procedures to produce kerogen concentrates that would be amenable to analysis. As was the case for coal, solid state NMR techniques fostered a resurgence of research devoted to characterization of oil shale in its native state. With the application of high-resolution proton CRAMP and carbon CP MAS spectroscopy, a great deal of fundamental information was obtained about the carbon and proton structure of these materials, about which there was little direct structural information known previously.

3.1 Structure Studies

The first application of NMR to the study of oil shales was reported in 1971, and this initial investigation was focused on the use of broadband ¹H NMR as a quantitative approach to predict oil yields that was less time consuming than Fischer assay methods.¹⁰⁰ Three years later, a more comprehensive study was reported in which pulsed ¹H NMR techniques were employed for oil shale characterization.¹⁰¹

Analyses of oil shale components by high-resolution ¹H and ¹³C NMR have been carried out on samples from the Green River formation that were thermally fractionated into naphtha, light distillate, heavy distillate and residue fractions.¹⁰² Resonances in the spectra were assigned to normal alkanes, and to methyl- and dimethyl-branched alkanes, and the compositions of the various fractions were reported. Relaxation time experiments were correlated to the intermolecular segmental motion of the carbon chains in separate fractions. Solution NMR studies that followed have focused on applications of NMR to oil shale processing.^{103,104} Two-dimensional NMR techniques have been applied to the characterization of shale oils.¹⁰⁵ Carbon and hydrogen functional group distributions for oils, obtained from eastern and western oil shales within the USA, were determined using DEPT and quaternary-only (QUAT) pulse methods for editing carbon spectra.¹⁰⁶

The first solid state ¹³C NMR spectra using CP enhancement techniques on native oil shales were reported in 1976,¹⁰⁷ however, the authors mentioned that the spectra were quite disappointing because of the lack of resolution between a broad aliphatic resonance band and a weak, partially resolved aromatic band. Later studies extended the CP measurements to include wide variety of oil shales.¹⁰⁸ Resing et al.¹⁰⁹ were the first to report CP MAS measurements on the aromaticity of a Colorado oil shale, the value of which was in basic agreement with that obtained by chemical degradation methods. In subsequent investigations, several laboratories performed CP MAS measurements in order to classify oil shale kerogens of varied origins and depositional environments throughout the globe.^{110–113}

Early studies were also concerned with interference from mineral matter, particularly carbonate minerals, with the signals arising from the organic carbon in shales.^{109,114} The general consensus reached was that spectra exhibited little interference from carbonates because of the long spin-lattice relaxation times of the minerals. For detailed investigations of the carbon structure of the organic fraction, NMR analyses were carried out on the kerogen concentrates that were prepared by removing the mineral matter by acid treatment (HCl or HF). Spectra of the kerogen concentrates were always found to be better resolved than those obtained from the raw shales, and even simple washing with HCl improved the quality of the spectra.^{111,115} The question remained, however, whether the preparation of concentrates by acid treatment had altered the chemical structure of the kerogen in the raw oil shale. A detailed study was carried out to address this issue, employing CP MAS techniques to characterize the organic carbon distributions in six oil shales and their isolated kerogen concentrates.¹¹⁶ It was determined that the raw shales and their corresponding kerogen concentrates had similar gross compositional features, e.g. carbon aromaticities, indicating that acid extraction did not significantly alter the chemical structure of the organic kerogen material. However,

Figure 8 CP MAS ^{13}C NMR spectra and f_a values of oil shale samples at various depths in the vicinity of a basaltic intrusion. Dark areas indicate regions of intrusion

carbohydrate structures if present in the original oil shales, were removed during acid extraction.

The utility of CP MAS NMR as a chemical elucidation method was demonstrated on a series of samples from a section of core taken from the Atlantic ocean, where a basaltic intrusion of magma had permeated the sediment during the Miocene period (see Figure 8).¹¹⁷ The thermal effects on the organic fraction were clearly visible in the spectra; samples closest to the basaltic intrusion zone clearly showed higher aromaticity values as a result of thermal cracking and subsequent loss of their long-chain aliphatic structures. Aromaticities derived from NMR were compared with results from more traditional vitrinite reflectance measurements, and it was concluded that NMR aromaticities were more sensitive and more quantitative to thermal changes in the kerogen structure.

NMR spectral editing using dipolar dephasing techniques has been applied to derive structural parameters for three oil shales from Colorado, Tennessee and Kentucky.¹¹⁸ Measurements were obtained on the native shales. Differences in carbon structure between the three shales were provided by the DD data, including the distribution of primary through quaternary aliphatic structures, protonated and nonprotonated aromatic groups, the number of methyl groups per aromatic

ring, the number of substituted or bridgehead carbon atoms per aromatic ring, and the minimum aliphatic chain length. A later investigation employed curve fitting procedures in conjunction with DD techniques to determine the distribution of carbon bonding types in a kerogen from the Green River Formation.¹¹⁹ Fourteen representative carbon functional groups were analyzed and these were used to derive an average structure for the kerogen. Analysis of the data indicated that the kerogen was composed of long-chain aliphatic residues as well as alicyclic ring structures, although relative proportions of each were not totally quantifiable on the basis of NMR results.

3.2 Resource Evaluation

The quality of the organic matter in oil shale has traditionally been used as the standard for its potential for bearing oil on heating. Conventional pulsed ^1H NMR has been employed as a rapid method of analysis for oil shale evaluation.^{108, 120–122} The method relies on the measurement of the amplitude of the free induction decay to assess the overall hydrogen content of the shale. In actuality, the measurement was simply a measure of the quantity of kerogen in the sample. To date, ^1H CRAMPS has not been employed for the analysis of oil shales.

With the development of ^{13}C CP MAS spectroscopy, a new method was introduced which has played a significant role in oil shale resource evaluation because it provides a direct means of analyzing aliphatic/aromatic carbon distributions in these systems, and thereby manifests an immediate relationship to yields of saturated oil products. Aliphatic structures tend to be hydrogen rich; thus oil shales having greater aliphatic carbon content were known to produce higher fractions of liquids than those more aromatic in nature.

The first CP MAS studies to establish a correlation between the aliphatic carbon content of oil shales and oil yields determined by traditional Fischer assay methods were performed by Maciel et al.^{123, 124} Several additional CP MAS studies followed on a wide range of kerogens and oil shales.^{125–128} The correlation between aliphatic carbon and oil yields was determined to be linear for samples spanning a diverse range of geological time periods, geographic locations and depositional environments. The excellent correlation between genetic potential, or the amount of oil and gas that an oil shale kerogen is able to generate, and fraction of aliphatic carbon has since been documented in several laboratories.^{129–133} Conversely, the aromatic carbon content has been shown to correlate with the carbon residue remaining after pyrolysis.^{115, 132–134} Solid state ^{13}C NMR has since been considered the paradigm for resource evaluation in the field, because the method relies on structure parameters that are closely identified with fuel yields. Moreover, the information is independent of the total kerogen content in the oil shale, which is often a misleading parameter for oil generation.

3.3 Oil Shale Conversion

Solid and liquid state NMR, in combination with elemental analysis and mass spectrometry, have provided valuable insight into the chemistry of oil shale conversion throughout the last two decades. From the perspective of processing, NMR has been attractive because it is capable of measuring directly

the changes associated with the carbon bonding distributions that occur as a function of temperature and other retorting parameters. Early studies involved liquid-state ^1H and ^{13}C NMR on oils produced from pyrolysis and hydropyrolysis of shales from eastern and western USA; a comprehensive set of average molecular structure parameters were derived for the hydrocarbon mixtures.¹³⁵ Research performed in several laboratories^{115,136–141} has combined CP MAS NMR measurements with data from elemental analysis to determine the degree of aromatization during oil shale pyrolysis.

Hershkowitz et al.¹³⁶ were the first to quantify the increase in aromatic carbon formed in pyrolysis of Colorado oil shale. Their experiments were carried out at a slow heating rate up to a temperature of 600 °C under high pressure (2600 kPa) N_2 or H_2 . The net increase in total aromatic carbon for the oil and residue products over that of the starting shale oil was determined by solution state and CP MAS ^{13}C NMR. The increase was rationalized in terms of aromatization of the aliphatic carbon functional groups and the associated evolution of light gases and oils that were composed of hydrogen-rich aliphatic species. Similar trends were observed in the pyrolysis studies of Green River and Kentucky oil shales,^{137,138} where increases in aromatic carbon content of 29% and 17% were reported, respectively. Consequently, it had been shown that aromatization of aliphatic structures in oil shales was indeed a facile thermal reaction, and that only by carefully controlling the pyrolysis temperature was it possible to minimize aromatization reactions responsible for oil loss.

4 OTHER FUELS

4.1 Petroleum

The earliest high-resolution ^1H NMR spectra of petroleum fractions, obtained at a frequency of 30 MHz, were reported in 1957.^{142–144} Two practical uses of the application of ^1H NMR in the petroleum industry appeared 2 years later, in 1959. A paper¹⁴⁵ was published which described NMR as a technique to evaluate the elemental hydrogen content of petroleum, and a patent¹⁴⁶ was issued in the same year concerning NMR as a method for process control for determining fuel quality on the basis of the degree of branching of alkylated aromatic hydrocarbons.

Although high-resolution ^1H NMR had proved to be valuable in the characterization of petroleum and petroleum fractions, the introduction of ^{13}C NMR in 1967 as a quantitative tool using time-averaged slow passage techniques¹⁴⁷ provided a prelude of what was soon to become a powerful analytical method. Nine years later, the first detailed ^{13}C NMR investigation of crude oils and petroleum fractions appeared using FT methods.¹⁴⁸ Replacement of continuous wave techniques by FT made the ^{13}C NMR characterization of crude oils and petroleum products more or less routine. Several conference proceedings and reviews have appeared in the literature which summarize much of the information that has been derived from NMR about the chemistry and structure of heavy crude oils and petroleum, including the use of NMR in petroleum exploration and as an oil logging tool.^{149–151}

Several fundamental advances have been realized in the elucidation of heavy oils by NMR. In 1981, Gillet et al.¹⁵²

presented and discussed numerous criteria necessary for obtaining quantitatively reliable structural parameters from NMR experiments. One year later, NMR was used to provide a 'fingerprint' of various crude oils.¹⁵³ SEBBORD pulse methods were used for spectral editing of carbon spectra of petroleum fractions, facilitating the discrimination of the different bonding schemes of aliphatic carbon structures, i.e. between CH , CH_2 , and CH_3 groups.^{154,155} The analysis provided sufficient information such that average structural parameters could be derived for these complex mixtures. Carbon chemical shifts and spin–lattice relaxation times were later used to characterize oil products.¹⁵⁶ Nitrogen compounds in crude oils have also been examined and identified with ^{13}C NMR.¹⁵⁷

The use of ^{33}S NMR as a tool for the characterization of petroleum oils¹⁵⁸ and an oxidized petroleum asphaltene¹⁵⁹ have been reported. The technique has met with limited success because of the considerable quadrupolar linewidths of sulfur combined with the large number of sulfur species present in these complex mixtures.

4.2 Peat

Humic substances have been described as the predominant fraction of the organic matter found in peat. Peat was formed in depositional environments where water had flowed near the surface of the peat profile, slowly but continually inundating the peat subsurface, and where anerobic conditions prevailed within the subsurface layers. These conditions led to the preservation, from oxidative and microbial processes, of the organic matter in peat which has always been thought to be derived from lignin from vascular plants.

An excellent treatise¹⁶⁰ on the use of ^{13}C CP MAS NMR as a structural tool for the investigation of sedimentary humic substances has appeared. The review covers the relevant literature concerning early liquid state and solid state NMR studies of aquatic and terrestrial sediments, and describes in detail recent CP MAS experiments on peat fractions from various geographical locations.

Early studies¹⁶¹ on humic acids and humins from holocene sediments were the first to suggest that CP MAS NMR can be used to distinguish between humic acids from terrestrial and aquatic environments on the basis of their carbon aromaticities. Source materials for the two sediments were entirely different: terrestrial sediments were based on lignin-derived material that was highly aromatic, whereas aquatic sediments were formed from primarily algal or microbial remains. In a subsequent paper,¹⁶² the same authors attributed the presence of aliphatic structures in marine humic acids to an algal source, and in terrestrial humic acids to lipid material. These initial observations provided the basis for understanding later NMR investigations on humic acids derived from peats.

In those subsequent studies,¹⁶⁰ CP MAS measurements were performed on isolated fractions of fulvic acid, humic acid, and humin from peats obtained from Minnesota, Okefenokee, and the Everglades. Absolute quantities of the aromatic and paraffinic structures, carboxyl, carbonyl and ether functional groups, and carbohydrates were determined and compared for individual fractions from the different peat samples. The data were used to determine the chemical composition of the varied structural components within peat samples from different

depositional environments, and the information was used to develop a model for the transformation of plant residues into humic substances. An investigation¹⁶³ published one year later focused on the use of ¹³C CP MAS spectroscopy, among other techniques, to identify structural changes that occur in humic acids during coalification through the stages of peat, lignite, and sub-bituminous coal.

4.3 Tar Sands

Tar sands are composed of complex mixtures of minerals containing aliphatic, heteroaromatic, and polycyclic aromatic compounds. Because of the strong intermolecular associations between molecules, organic matter in tar sands is often considerably viscous. Bitumen and heavy oil fractions of tar sands from different geographical locations differ widely in chemical composition and physical properties.

To date, there have been few published reports on the use of NMR for characterizing tar sands. Two early studies have attempted to characterize organic-inorganic interactions directly in heavy oil/bitumen-derived solids using ¹³C CP MAS NMR.^{164,165} A subsequent investigation¹⁶⁶ used ¹H CRAMPS to provide information on the types of hydrogen functionality that were present at the surface of tar sand residues. The data indicated that hydroaromatic structures were bound more strongly to the mineral surfaces, and that residues of tar sands after pyrolysis became highly aromatic in nature. Relaxation time (T_1) measurements¹⁶⁷ were used to determine the rates of intermolecular association of a tar sand bitumen after its thermally induced dissociation. Separate studies were carried out whereby viscosities of tar sand bitumens could be calculated from T_2 relaxation time measurements performed at room temperature.¹⁶⁸ Viscosities of bitumens from three US tar sands were correlated to weighted T_2 relaxation rates for semiliquid, mobile solid-like and rigid phases.

1 INTRODUCTION

The dramatically increased use of acidifying fossil fuels has, during the last decades, caused a significant pH-drop of rain and surface waters in large parts of the industrialized world. In areas situated on noncalcareous aluminosilicate bedrocks, the solid phases have thereby responded by mobilizing aluminum. As a result, it has been found that this element, which was previously thought to be quite harmless, can cause severe damage to water-living plants and animals, and also to man. In fact, some researchers claim that the main ecological danger with surface water acidification is not the increased proton concentration per se, but rather the increased aluminum concentration it causes.¹

What has made this area particularly interesting from an ²⁷Al NMR point of view is that it has been shown unambiguously that different chemical forms of aquatic aluminum exert highly different bioavailabilities and toxicities.² Thus, with regard to water-living organisms, Al bound to organic compounds seems practically nontoxic while, at the same time, the most efficient route to uptake in man is obtained by reacting the aluminum ion with certain organic compounds (e.g. citric acid or maltol). These findings underline the need for increased knowledge about the chemical speciation of Al(III) under different conditions, a subject for which solution ²⁷Al NMR has proved to be a highly valuable tool.

It should also be pointed out that there are numerous other applications in which solution ²⁷Al NMR can provide a better understanding for the chemistry of that application. Thus, hydrolyzed aqueous Al(III) solutions are used for raw and wastewater clarification, as retention agents in the paper industry, and as the active agent in antiperspirants. Aluminum compounds in nonaqueous media are excellent Lewis acid catalysts and are used in many catalytic reactions for the stereospecific polymerization of α -alkenes (Ziegler–Natta) and for Friedel–Crafts alkylation or acylation.

Several reviews^{3–6} on the subject of aluminum-27 NMR have been published, the most recent and comprehensive by Akitt.⁶ In this article most of the original papers reviewed by Akitt will not be separately referenced when referred to, and the reader is recommended to consult the article by Akitt. Also,

with regard to tabulations of registered chemical shifts and linewidths of different chemical species, Delpuech⁴ or Akitt⁶ should be consulted.

2 PROPERTIES AND OPERATIONAL CONSIDERATIONS

From the strict aspect of NMR receptivity, the ²⁷Al nucleus is one of the 10 most sensitive nuclei of the Periodic Table. Its receptivity is 1170 times that of ¹³C and 0.206 times that of ¹H. This implies that, under favorable conditions, good signal/noise ratios can also be obtained from highly dilute (<0.0001 M) solutions.⁷ In contrast to these two nuclei, however, ²⁷Al is a quadrupolar nucleus ($I = 5/2$; $Q = 0.149 \times 10^{-28} \text{ m}^2$) which, on the one hand, implies that problems with long relaxation times and, accordingly, low pulse repetition rates rarely occur. On the other hand, the linewidths of the appearing signals are strongly dependent on the symmetry (electric field gradient) of the species causing the signal. The reported linewidths range from a few Hz for highly symmetric octahedral or tetrahedral complexes up to linewidths so high that they easily pass the limit of detection.

In many cases, the ²⁷Al NMR spectrum of a given solution contains a mixture of broad and narrow resonances. This can either result from the simultaneous occurrence of several coexisting species or from the presence of a polynuclear species containing Al in several coordination environments. An often cited example of this latter situation is the spectrum from $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$, cf. spectrum (a) of Figure 1 which at room temperature contains one signal from the central tetrahedral Al ion 25 Hz wide and one signal from the 12 octahedral ions 8000 Hz wide. Unless the presence of this latter signal is expected, it may then easily be missed.

An implicit problem with wide and/or undetected signals is that the integrated areas of detected signals do not correspond to the total Al concentration in the sample. This is an obvious fact for undetected signals, while for broad but detected signals it results from a partial relaxation during the dwell time between excitation pulse and data acquisition.

Akitt⁶ states, as a rough guide, that to obtain better than 90% quantitative information from such resonances, the total spectral width covered must be at least six times the width of the observed signal. Other prerequisites for a successful quantification of the spectrum are to suppress the occurrence of baseline roll and to identify correctly the baseline position, tasks, which are by no means trivial when dealing with spectra containing overlapping broad and narrow resonances.

Due to these difficulties, one should always relate the ²⁷Al spectrum of an unknown sample to that of an external standard of known concentration and containing all Al in a single species with a narrow resonance line. By comparing the integrated area from this signal with the sum of the integrated area from the sample, conclusions with regard to 'missing Al' can be drawn. Furthermore, the absolute concentration of each resolved resonance can be evaluated and this is crucially important when the identity of the species causing the resonances is to be interpreted.

Overlapping resonances also pose a difficult problem which, to some extent, can be solved by using spectral deconvolution techniques. The major problem is, however, that the number of

Figure 1 ^{27}Al NMR spectra showing the thermal evolution of a 0.035 M solution of $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ ($\text{Al}_{\text{tot}} = 0.45 \text{ M}$) at 85°C . Spectra were recorded in situ at 130.3 MHz as a function of aging time: (a) 0; (b) 6; (c) 12; (d) 18; (e) 24; (f) 30; (g) 38; (h) 80; (i) 130 h. Inset shows expansion in the tetrahedral region. (Reproduced by permission of the American Chemical Society from G. Fu, L. F. Nazar, and A. D. Bain, *Chem. Mater.*, 1991, **3**, 602)

species which together result in a broad ill-resolved spectrum cannot be determined, and thus the basic requirement for spectral deconvolution cannot be fulfilled. However, one resonance that is always discernible is the signal from free Al^{3+} and it can therefore be stated that ^{27}Al NMR, even in the worst case, always functions as an unique ‘ion-selective electrode’ for Al^{3+} .^{8,9}

The best choice for the external standard is probably an acidic aqueous solution of aluminum perchlorate [e.g. 0.1 M $\text{Al}(\text{ClO}_4)_3$ in 0.1 M HClO_4] [linewidth 2 Hz for $\text{Al}(\text{H}_2\text{O})_6^{3+}$], which might then also serve as a chemical shift standard (see Section 3.1). Another standard in use is an alkaline aluminate solution, but for this standard the resonance is broader [linewidth 10 Hz for $\text{Al}(\text{OH})_4^-$]; the excess alkali present in this standard slowly dissolves Si from glass with the risk of aluminosilicate complex formation (cf. Section 4.2) and the standard must also be protected from atmospheric CO_2 to avoid $\text{Al}(\text{OH})_3(\text{s})$ precipitation.

There are, in principle, two ways in which the external standard can be applied. Either the time domain of the FID is employed by calibrating the area of the reference FID for a given number of transients and spectral width (i.e. running the spectrometer in the absolute intensity mode), or the frequency domain is employed by arranging the standard in a capillary in the center of the sample tube. The relative ratio between the two compartments can, in this second case, be determined by measuring the $\text{Al}^{3+}/\text{Al}(\text{OH})_4^-$ integral ratio when the compartments are filled with the two standards described above and containing equal $\text{Al}(\text{III})$ concentrations.

An obvious drawback, when using the concentric sample tube technique with Al^{3+} as the reference standard, is that the signal from the reference will coincide with the signal from the Al^{3+} in the sample. As shown by Koch,⁷ this problem can be avoided if the reference also contains a suitable amount of Eu^{3+} , a lanthanide shift reagent moving the reference Al signal to a position where no interference with sample signals occurs.

As a final operational warning, it should be pointed out that many of the modern NMR spectrometers have probes manufactured of an aluminum-containing ceramic material and

that these solid state $\text{Al}(\text{III})$ ions give rise to a broad high-frequency resonance. When working with samples containing broad signals, this resonance must be subtracted by running a blank sample or erroneous conclusions will be drawn.

3 ALUMINUM-27 NMR PARAMETERS

The most commonly used parameters of aluminum-27 are chemical shift, spin–spin coupling, and nuclear spin relaxation, and they will be discussed separately in that order.

3.1 Chemical Shifts

The acidic perchlorate solution is, as mentioned, the best reference ($\delta = 0$) for external use, since the uncorrected shift value is very close to that obtained after susceptibility correction. It could be convenient to prepare the reference sample in deuterium oxide since this sample can then act as both standard and lock. However, a small low-frequency isotope shift of 0.25 ppm for the hexaaqua cation must be corrected for if high precision measurements are required.

Aluminum(III) interacts with other molecules in solution to an extent that is determined by the donor ability of the species present. Broadly speaking, aluminum-27 chemical shifts in diamagnetic solutions cover roughly a range of 300 ppm and this range can be subdivided grossly into three shift regions: (i) alkylaluminum compounds with resonances at 100 ppm or more to high frequency of the hexaaqua reference; (ii) tetrahedrally coordinated aluminum compounds with shifts between 140 and 40 ppm; and (iii) octahedrally coordinated aluminum between 40 and -46 ppm. The observed chemical shift is thus broadly diagnostic of the actual coordination state, although there are significant overlaps between the regions mentioned. The complex ion AlI_4^- , for instance, has an absorption at -26.7 ppm, i.e. to significantly lower frequency than the general expectation, and the hexamethylphosphoric triamide (HMPA) aluminum complex $[\text{Al}(\text{HMPA})_4]^{3+}$ has a shift value of 34.1 ppm. For aluminum salts in mixed dimethyl sulfoxide (DMSO)/dimethylformamide (DMF), seven signals appear around 0 ppm indicative of seven pure and mixed solvates, which provides evidence of six coordination.

One may ask whether the observed low-frequency shifts in aluminum species are due to increased hybridization of atomic orbitals or only to increased overall electron density at aluminum as the number of donating ligands increases. The existence of additivity in structurally related series of compounds seems to support the electron donation hypothesis. Thus, the order of successive signals in $\text{AlX}_n\text{Y}_{4-n}$ or $\text{AlX}_n\text{Y}_{6-n}$ is strictly monotonic, and in most cases with a constant frequency interval between two consecutive signals. However, the obtained shifts of mixed halide anions do not vary linearly with the number n of ligands, but Malinowski¹⁰ has shown that a pairwise additivity model can account for the observed shifts in such series.

3.2 Spin–Spin Coupling Constants

Although well-resolved coupling patterns are of a fundamental interest to structural chemists, such information

rarely occurs in aluminum-27 NMR spectroscopy due to the quadrupolar properties of that nucleus. Scalar coupling between two spins will only appear if the spin-lattice relaxation time, T_1 , of both nuclei are sufficiently long to fulfill the relationship $2\pi JT_1 \gg 1$. If $2\pi JT_1$ for one nucleus, like aluminum, is small enough, then no splitting will be noticed for the signal of the other nucleus. A partly collapsed pattern will be observed in borderline cases when this term is close to unity. The expected sextet splitting pattern due to coupling to a spin- $\frac{5}{2}$ nucleus will only appear in highly symmetrical complexes, i.e. where the electric field gradient (EFG) at aluminum is small.

Most of the reported scalar couplings refer to observations of aluminum bound to ^1H , ^2D , ^{31}P , or ^{14}N nuclei. The existence of 12 coupled equivalent protons in aluminum borohydride was proven by two-bond coupling, giving a 13-line multiplet in amine adducts. Conclusive structural information was also obtained for alkali tetrahydroaluminates in dimethoxyethane, where a quintuplet was seen. ^{27}Al - ^{31}P coupling has been reported for phosphine adducts of AlCl_3 and AlBr_3 , octahedral and tetrahedral solvates of the Al^{3+} ion, and mixed solvation complexes. Surprisingly sharp ^{27}Al - ^{14}N coupling patterns are obtained with anions such as $\text{AlCl}_3(\text{SCN})^-$ and $\text{AlCl}_2(\text{SCN})_2^-$, whose structures are thus clearly verified. The observation of multiplets in the spectra of both quadrupolar nuclei provides interesting support to the claim that EFGs are generated near the nuclei. If the symmetry of the whole molecule determined the low EFG point, then only one such point could exist, but if the local symmetry is the important factor then there could be several such points.

Values of scalar couplings can also be obtained from lineshape analysis of partially averaged out multiplets. The existence of contact ion pairs of LiAlMe_4 and NaAlMe_4 in ether and tetrahydrofuran has been shown by such calculations. Analysis of the carbon spectrum of the terminal and bridging methyls in Al_2Me_6 is one of the rare examples where a spin- $1/2$ nucleus is coupled to two equivalent spins $\frac{5}{2}$. The exceptionally small $^1J(\text{Al}, \text{C})$ coupling of 19 Hz found for the bridging methyl indicates the formation of a rather strong Al-Al bond, mainly s in character, and a consequent reduction in the s-electron contribution in the bridge bond.

Splittings between ^{27}Al and ^{31}P are typically in the range of 250–290 Hz for one-bond couplings and 12–30 Hz for two bonds. The two-bond coupling increases from 19.9 to 30 Hz on going from a hexacoordinate solvate, e.g. $\text{Al}(\text{TMPA})_6^{3+}$, to the tetracoordinate complex $\text{Al}(\text{HMPA})_4^{3+}$. This is in accord with the classic dependence of J on the proportion of s character in the aluminum orbitals, e.g. $\frac{1}{6}$ and $\frac{1}{4}$ for the d^2sp^3 and sp^3 hybridizations, respectively. The magnitudes of ^{27}Al - ^{13}C in AlMe_4^- being ca. 70 Hz illustrate the predominant contribution of Fermi contact interaction on the basis of the correlations proposed in the literature for such couplings.

3.3 Nuclear Spin Relaxation Processes

Aluminum-27 relaxation is dominated by quadrupolar interactions, as expected from its relatively high quadrupolar moment. If certain requirements are fulfilled such as: (i) time-independent coordination to the aluminum nucleus; (ii) extreme narrowing conditions; and (iii) isotropic chelate

reorientation described by a single correlation time, then the quadrupolar relaxation rate can be described by the classical equation [equation (1)] by Abragam:

$$1/T_{1Q} = 1/T_{2Q} = \frac{3\pi^2}{10} \frac{(2I+3)/I^2(2I-1)}{(1+\eta^2/3)} (e^2qQ/h)^2 \tau_c \quad (1)$$

where e^2qQ/h is the quadrupolar coupling constant, of which eq is the main component of the electric field tensor, and η is the asymmetry parameter.

Species with high symmetry, like certain tetrahedral or octahedral complexes, in which $q = 0$, have relaxation rates as small as a few Hz. In many of these cases, other relaxation mechanisms come into play, such as scalar relaxation for aluminum halides and dipolar relaxation for alkylaluminum compounds. Mixed scalar and quadrupolar relaxation can be noticed in symmetrical species and the scalar part can be used to determine coupling constants between Al and other quadrupolar nuclei. If the extreme narrowing condition is not fulfilled, i.e. where the rate of molecular reorientation is lower than the spectrometer frequency, then the above equation is not applicable. For instance, if the aluminum nucleus is situated in a colloidal particle, then $\omega\tau_c \gg 1$ and $T_1 = T_2$. The relaxation behavior becomes much more complex now with a multiexponential relaxation consisting of, in ideal cases, three superimposed exponential decays and a super-Lorentzian lineshape. However, lines are normally too broad to be detected due to long correlation times. However, if chemical exchange between bound and free aluminum is fast enough, then the nonexponential behavior in the bound state will be detected in the narrow resonance of the free aluminum cation.

3.4 Chemical Exchange Processes

In the slow exchange limit, where two separate signals are detected, the exchange broadening is given by equation (2):

$$1/T_2 = 1/T_{2Q} + 1/\tau_e \quad (2)$$

where T_2 is the apparent relaxation time of one of the exchanging species, T_{2Q} is the relaxation time of that species in the absence of exchange, and τ_e is the lifetime of the nucleus in the part of the population that gives rise to the signal.

When two or more species are undergoing fast exchange on the NMR timescale, then the resulting linewidth will be the weighted mean over exchanging sites. This situation is equivalent to considering an averaged EFG tensor $q = p_A q_A + p_B q_B + \dots$, where p_A and p_B , etc. are mole fractions of those species involved in the dynamic process. This process is of no major interest for spin- $1/2$ nuclei since such conditions will only afford a single narrow line. In the case of quadrupolar nuclei, however, the linewidths of the species involved can vary by orders of magnitude and significant changes in linewidths will be noticed as the relative proportions of the species vary. Hence, the linewidth of ^{27}Al in aqueous solutions will vary with both pH and temperature, since these conditions influence the degree of hydrolysis yielding $\text{Al}(\text{H}_2\text{O})_5(\text{OH})^{2+}$ (cf. Section 4.1).

Further complications will be seen in cases where the rate of exchange is fast enough to cause coalescence, but still not too

different to the rate needed to cause coalescence of chemically shifted lines. In such cases, where exchange rates are within the NMR timescale window, the magnitude of the chemical shifts must be taken into account. In variable temperature studies, such conditions can cause a line to narrow in the same sense as the natural quadrupolar relaxation.

4 THE AQUEOUS SOLUTION CHEMISTRY OF ALUMINUM(III)

An investigation of an aquatic chemical system can aim at several different levels of complexity. The first level, which also constitutes an absolute prerequisite for all subsequent levels, is that the compositions, i.e. stoichiometries, of the appearing species are determined. The second level then is to determine the interrelation between the analytical composition of the solution and the amount of different species formed in it. These two levels have traditionally been investigated by means of potentiometric and spectrophotometric measurements, with data being analyzed under the presumed condition of chemical equilibrium.

A third level in the investigation of an aquatic system is to determine the three-dimensional structures of the appearing species, and a fourth level is to determine the interconversion rates between the species and to relate these back to their chemical structures.

As will be shown in the following, ^{27}Al NMR provides a valuable tool, when carefully used, at all these four levels. Ideally, however, it should not be viewed as a self-contained analytical technique but should be supplemented with traditional solution chemistry methods mentioned above and, whenever possible, with measurements of other nuclei in the sample. Furthermore, to fulfill the requirement of level two above, the law of mass action is probably invaluable. This implies that constraints with regard to basic solution thermodynamics, such as high-precision concentration control, temperature control, activity factor control, and so on have to be obeyed.

4.1 The Hydration and Hydrolysis of Al^{3+}

The aluminum ion is one of the most typical examples of a hard acid and, as such, prefers coordination to hard bases such as oxygen and fluorine. This implies that water molecules form relatively strong bonds to the Al^{3+} ion and it has been found that few other solvents are able to replace water from its first coordination sphere. It has also been found that practically invariant chemical shift values are obtained for acidic aluminum perchlorate, chloride, bromide, iodide, and nitrate solutions, thereby implying that the presence of contact ion pairs with these anions is negligible.

The number of water molecules in this coordination sphere can be determined via ^{27}Al NMR measurements of solutions containing mixtures of water and organophosphates, R_3PO . In these mixtures, and depending on the $\text{H}_2\text{O}/\text{R}_3\text{PO}$ ratio, seven different resonances can be recorded, corresponding to the formation of $\text{Al}(\text{H}_2\text{O})_{6-n}(\text{OPR}_3)_n^{3+}$; $0 \leq n \leq 6$. Thus, six water molecules surround the Al^{3+} ion and, from the narrow appearance of the signal, it can be concluded that these are coordinated in a highly regular, octahedral manner.

This species has also been studied by ^{17}O and ^1H NMR, through which it has been shown that while the rate of whole water molecule exchange is relatively slow, $k = 1.3 \text{ s}^{-1}$, the rate of proton exchange is much faster, $k = 10^5 \text{ s}^{-1}$.

When a strong base (i.e. OH^-) is gradually added to a moderately concentrated ($\leq 0.1 \text{ M}$) $\text{Al}(\text{H}_2\text{O})_6^{3+}$ solution, a number of consecutive changes in its ^{27}Al spectrum can be observed. The linewidth for the resonance corresponding to Al^{3+} , $\delta = 0 \text{ ppm}$, increases and its integrated area decreases. A new signal appears at $\delta = 4.0 \text{ ppm}$ with a linewidth of $\sim 500 \text{ Hz}$. The intensity of this resonance passes a maximum at around 1–1.5 OH^- added per Al^{3+} and is gradually replaced by a narrow resonance ($\sim 25 \text{ Hz}$) at $\delta = 62.5 \text{ ppm}$ together with a very wide (8000 Hz) resonance at 12 ppm. At 2.2–2.5 added OH^- per Al^{3+} , the solution gradually turns milky due to the formation of $\text{Al}(\text{OH})_3(\text{s})$ so that, at 3 OH^- added per Al^{3+} , no signal intensity is obtained. Finally, at >3 added OH^- per Al^{3+} , a new resonance appears at 80 ppm (10 Hz wide). Its intensity increases until all $\text{Al}(\text{OH})_3(\text{s})$ has dissolved and then stays invariant up to very high pH values.

These are all effects from the hydrolysis of Al^{3+} and it has been shown that the broadening of the Al^{3+} signal is caused by a fast exchange with the species $\text{Al}(\text{OH})(\text{H}_2\text{O})_5^{2+}$. By assuming a chemical shift of 0 ppm and a linewidth of 620 Hz for this species, Akitt and Elders¹¹ found that the experimental line broadening at low Al concentration ($\leq 0.005 \text{ M}$) corresponds to a $\text{p}K_a$ for $\text{Al}(\text{H}_2\text{O})_6^{3+}$ of 4.93, a value in good agreement with available thermodynamic data. The variation of activity coefficients with concentration was, however, neglected and the numerical value of the equilibrium constant was therefore found to vary with aluminum concentration.

The decrease in area with increasing base additions is balanced by the area found for the signal at 4.0 ppm. This implies that a new species, exchanging slowly on the NMR timescale, is being formed. Until recently, and because of its appearance as a solid phase, this resonance has generally been assigned to the species $\text{Al}_2(\mu\text{-OH})_2(\text{H}_2\text{O})_8^{4+}$. This was questioned by Akitt et al.¹² who, based on ^1H measurements of dried samples transferred to acetone, suggested instead the formation of a species $\text{Al}_3\text{O}_2(\text{OH})_4(\text{H}_2\text{O})_8^+$. The $\text{OH}^-/\text{Al}^{3+}$ ratio assigned to this species must however be questioned, since it is higher than in the species known to succeed it with increasing $\text{OH}^-/\text{Al}^{3+}$ ratio, the $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ ion.

As already mentioned, this species consists of a central symmetric AlO_4 tetrahedron resonating at 62.5 ppm and 12 surrounding distorted AlO_6 octahedra, giving rise to the very wide signal at 12 ppm. The formation of this species depends critically on a supersaturation with respect to crystalline $\text{Al}(\text{OH})_3(\text{s})$, gibbsite. This means that its very existence depends on kinetic restraints with regard to $\text{Al}(\text{OH})_3(\text{s})$ precipitation. It has therefore been widely questioned whether this species is ever formed under natural water conditions.

To answer this, Furrer et al.¹³ recently simulated a natural neutralization process by flowing a highly dilute Al^{3+} solution over granulated marble and found, by ^{27}Al NMR, that indeed considerable amounts of $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ were formed.

The resonance finally appearing at 80 ppm in alkaline solutions can, without doubt, be assigned to the aluminate, $\text{Al}(\text{OH})_4^-$, ion. It has been shown,¹⁴ that up to NaOH concentrations of $\sim 5 \text{ M}$, this ion is the sole hydrolysis product.

Figure 2 ^{27}Al NMR spectra at 104.2 MHz of a concentrated ($\text{Al}_{\text{tot}} = 6.0 \text{ M}$) sample with 2.5 OH^- per Al^{3+} as a function of temperature. The line at 80 ppm is due to the standard capillary. The amounts of aluminum visible in the spectra are 14% at 25°C, 30% at 70°C, and 39% at 80°C. (Reproduced by permission of The Royal Society of Chemistry from J. W. Akitt, J. M. Elders, X. L. R. Fontaine, and A. K. Kundu, *J. Chem. Soc., Dalton Trans.*, 1989, 1889)

Above this limit, a certain loss in integrated area is observed, possibly pointing to the formation of other species.

At high aluminum concentrations, and strongly depending on preparation variables such as total concentration, neutralizing agent, base injection velocity, reaction temperature, and aging time, the significance of $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ diminishes. The complex(es) replacing it result in very ill-resolved ^{27}Al spectra^{12,15} (cf. Figures 1 and 2) and, based on very complex ^1H spectra, it was concluded that a wide range of products is formed.¹² These are all of high molecular weight, coordinate approximately 2.5 OH^- per Al^{3+} , and may contain tridecamer-like subunits in their structures.

4.2 Complexes with Inorganic Ligands

A basic requirement for a ligand to form an inner sphere complex with Al^{3+} in water is that it must be able to compete with and replace water molecules of $\text{Al}(\text{H}_2\text{O})_6^{3+}$. This restricts the number of possible ligands to the fluoride ion and to ligands coordinating via oxygen ions, i.e. sulfate, carbonate, phosphate, and silicate, but also tungstate, molybdate and gallate. Since the water exchange rate of $\text{Al}(\text{H}_2\text{O})_6^{3+}$ is slow

on the NMR timescale, so generally is the ligand exchange rate. Hence, appearing complexes normally form separate resonances in the ^{27}Al spectrum at low temperatures which, due to the dominating quadrupolar relaxation mechanism for ^{27}Al , regularly become narrower on heating. Also, the ligand exchange rates can be suitably studied by variable temperature measurements. These measurements are, however, sometimes obscured by strongly temperature dependent equilibrium constants, and even the formation of 'new' complexes at high temperatures.

With F^- , it is well known that the Al^{3+} ion reacts with the formation of AlF_n^{3-n} ($0 \leq n \leq 6$). Of these species, only the first two and the last have been characterized by ^{27}Al NMR. The resonances for AlF_2^{+} and AlF_6^{3-} are both wide (620 and 890 Hz, respectively), while that for AlF_3 is a septet [$J(\text{Al}, \text{F}) = 19 \text{ Hz}$] which when decoupled results in a line 17 Hz wide. The chemical shift values are all close to zero (0.7, 1.3, and -1.2 ppm), strongly indicating that the whole series should be written as $\text{Al}(\text{H}_2\text{O})_{6-n}\text{F}_n^{3-n}$ ($0 \leq n \leq 6$). The profound effect of asymmetry is very clear and this system is much more conveniently studied with ^{19}F NMR spectroscopy.¹⁶

With SO_4^{2-} , two well-resolved resonances can be observed at -3.3 ppm and -6.7 ppm . These probably originate from the formation of $\text{Al}(\text{H}_2\text{O})_5\text{SO}_4^{+}$ and $\text{Al}(\text{H}_2\text{O})_4(\text{SO}_4)_2^{-}$, respectively. The almost additive effect of substituting one or two water molecules with ligands is a regular, but not general, feature of ^{27}Al spectroscopy. When evaluating the formation constant for AlSO_4^{+} from the signal at -3.3 ppm , the value obtained is approximately three orders of magnitude lower than the value obtained from potentiometric measurements. The conclusion has therefore emerged that SO_4^{2-} mainly interacts with Al^{3+} via the formation of an outer sphere complex, $\text{Al}(\text{H}_2\text{O})_6\text{SO}_4^{+}$. Indirect support for this view is provided by the fact that the resonance for Al^{3+} in sulfate solutions is situated 0.2 ppm to higher frequency than in perchlorate solutions.

It has long been known that strong complexes are formed between Al^{3+} and orthophosphate. Their characterization has proved notoriously difficult, however, partly because of their formation at very low pH and partly because of the onset of precipitation of $\text{AlPO}_4(\text{s})$ at $\text{pH} \geq 3$. The NMR technique is more or less ideally suited for characterizing this system since not only ^{27}Al but also ^{31}P can be employed with high sensitivity. Such measurements have shown that the system is also highly complex with regard to the number of species that can form. On the basis of only seven strategically selected samples, Wilson et al.¹⁷ were able to identify five different Al environments and at least 11 different PO_4 environments. Based on an assumed proportionality between the partial charge on the P atom and its chemical shift, Mortlock et al.¹⁸ have attempted to assign the resonances appearing at very high concentrations. From unpublished work by the author, the most acidic complexes at much lower concentrations, $\sim 10^{-2} \text{ M}$, seem to be $\text{Al}(\text{H}_2\text{PO}_4)_2^{2+}$ ($\delta_{\text{Al}} = -3.3 \text{ ppm}$; $\delta_{\text{P}} = -7.5 \text{ ppm}$ vs. 85% H_3PO_4) and $\text{Al}(\text{H}_2\text{PO}_4)_2^{+}$ ($\delta_{\text{Al}} = -7.3 \text{ ppm}$; $\delta_{\text{P}} = -6.9 \text{ ppm}$). Much work, however, remains to be carried out until this system is fully characterized. This is probably also true with respect to interactions between Al^{3+} and multidentate phosphates.

The main products formed by the interaction between Al^{3+} and silicates in acid solution are different solids. Only a few reports describing soluble complexes have appeared and no

solution NMR data have been reported. In mildly alkaline solutions, $9 \leq \text{pH} \leq 12$, the silicate ion polymerizes with the formation of a large number of chain, ring, cage, and network silicates. Aluminum, in the form of $\text{Al}(\text{OH})_4^-$, can be incorporated into these structures and its chemical surrounding can thereby be described in the form of $\text{Al}(\text{OH})_{4-n}(\text{OSi})_n$ units. For $0 \leq n \leq 4$, the effect of this substitution is almost linear with n , each exchange resulting in an upfield shift of 5 ppm.¹⁹ More detailed information about the structures of these complexes is obtained from ^{29}Si NMR spectroscopy.²⁰

Vanadate, molybdate, and tungstate are three anions known to form polymeric anions in acidic solution. They are also known to incorporate suitably sized foreign ions into what are called heteropolyanions. Due to their difference in size, their interactions with Al^{3+} are quite divergent. Thus, with the smallest vanadate ion, no interactions can be recorded. With the molybdate ion, a single complex with octahedral Al symmetry, $\text{Al}(\text{OH})_6\text{Mo}_6\text{O}_{18}^{3-}$, is formed, while with the large tungstate ion, aluminum can be incorporated both in tetrahedral and octahedral form. The formation of $\text{Al}(\text{OH})_6\text{Mo}_6\text{O}_{18}^{3-}$ has been fully characterized through the use of quantitative ^{27}Al NMR in combination with potentiometric methods.²¹

As described in Section 4.1, $\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ is a major hydrolysis product of Al^{3+} . By exchanging the central AlO_4 tetrahedron of this species for a GaO_4 tetrahedron, a ternary complex of even higher stability results.²² The reason for this is that the size of GaO_4 is more ideal, thereby resulting in a less strained structure. This is directly reflected in the linewidth of the resonance for Al_{12} , which decreases by almost 50%

4.3 Complexes with Organic Ligands

In aqueous solution, the aluminum ion forms complexes of great stability, preferentially with ligands containing strongly basic O atoms (aliphatic and aromatic hydroxylate, carboxylate, phosphate and phosphonate groups). Because of the chelate effect, complexes of higher stabilities are formed by bidentate and polydentate ligands, in which appropriately situated N atoms (amines) and carbonyls can also act as coordinating groups. A characteristic feature for this complexation is that it occurs in competition with ligand protonation and that, therefore, the speciation is strongly pH and Al/ligand ratio dependent. Many of the ligands also form bridging polynuclear complexes with Al^{3+} , especially at low ligand excess and near neutral pH, where the formation of mixed hydroxo ligand complexes is considerable.

Aluminum-27 NMR has been widely applied to the study of these systems but, with few exceptions, the resonances are broad and the resulting spectra are complex and ill-resolved. Assignments and interpretations based on such data alone should be regarded as highly tentative. By also extending the measurements to the ligand nuclei, i.e. ^1H , ^{13}C , and ^{17}O , the reliability of species identification can be highly improved.²³ Unfortunately, however, these measurements must be performed at very high concentrations, and the data generated cannot be used for a proper thermodynamic characterization of the complexes.

There are, in principle, two different situations in which the complexation behavior of Al^{3+} is greatly simplified. One situation is when it is exposed to a more than threefold excess

Figure 3 Variable pH ^{27}Al NMR spectra of $\text{Al}(\text{mpp})_3$ (left; 0.02 M) and of $\text{Al}(\text{dpp})_3$ (right; 0.03 M). (Reproduced by permission of the American Chemical Society from W. O. Nelson, T. B. Karpishin, S. J. Rettig, and C. Orvig, *Inorg. Chem.*, 1988, **27**, 1045)

of a strong bidentate ligand devoid of bridging properties, such as dicarboxylic acids, catecholates, 3-hydroxy-4-pyrones, and 3-hydroxy-4-pyridinones. The gradual increase in pH of such solutions results in the consecutive formation of three complexes, $\text{Al}(\text{H}_2\text{O})_{6-2n}\text{L}_n$ ($0 \leq n \leq 3$). The resonances from these complexes are often resolved²⁴ (cf. Figure 3) and an additive effect of ligand substitution is regularly encountered.

The other situation is when an excess of an aminopolycarboxylic acid, such as NTA or EDTA, is applied. The predominating complex is then $\text{Al}(\text{H}_2\text{O})_n\text{L}$ ($n \leq 2$) and the hydrolysis of the remaining water molecules²⁵ can be recorded in the ^{27}Al NMR spectra as a function of pH.

Much of the work performed on Al complexation during the past decade has been motivated by the involvement of Al in a number of toxic biological processes. In these investigations, low molecular weight substances of relevance for the uptake of Al have been studied. Recently, the ^{27}Al NMR technique has also been used to study high molecular weight protein complexation. With albumin,²⁶ a broad resonance at ~ -7 ppm was recorded and from the maximum intensity of the signal it was concluded that each albumin molecule can coordinate approximately three Al^{3+} ions. A considerable excess of Al is however needed to reach saturation, and it can therefore be concluded that the complexation strength of albumin is relatively low.

The coordination of Al^{3+} to ovotransferrin and its half-molecules was studied in the presence of the synergistic anions carbonate and oxalate.²⁷ Surprisingly narrow resonances (~ 200 – 400 Hz) in the octahedral range were obtained and, supported by ^{13}C data, an assignment with regard to N- and C-terminal site complexation was made. Based on several ^{27}Al NMR arguments, it was concluded that the molecular motion of this protein is well outside extreme narrowing.

5 THE ANHYDROUS SOLUTION CHEMISTRY OF ALUMINIUM(III)

Because of the marked solvent dependence of the aluminum nucleus, NMR chemical shifts for solvated aluminum ions have long been used as a direct probe of cationic solvation. It is thus possible to construct a solvent classification scheme for Al(III), according to the behavior of salts like halides or perchlorates when dissolved in a given choice of solvents. Preferential solvation has also been studied in mixed solvents, normally a mixture of two strongly donating solvents.

Solvents of common use span from inert or very weak donicity solvents like hydrocarbons, via weakly donating ones like chlorinated hydrocarbons, ethers, and acetonitrile, and finally to strong aprotic donors like DMSO, DMF, HMPA, or protic donors like alcohols. Studies in very weak donicity solvents have normally been restricted to aggregation studies, like monomer–dimer equilibrium studies of trialkylaluminums.²⁸ Aluminum chloride remains more or less totally as a dichloro-bridged dimer in such solvents. ²⁹Si NMR of species such as silyl ‘cations’ are better NMR probes for the classification of these very weakly donating solvents.²⁹

Ion-pairing effects are of course of major concern if organic solvents, are used. However, for a large sphere cation like Al(III), only first coordination sphere effects will normally be noticeable, and changes in charge polarization on going from inner to outer sphere complexation of the ligand nuclei will also be largely suppressed for such a large positive cation sphere.

5.1 Complexes with High Donicity Aprotic Solvents

The possibility of observing resolved signals will increase in the case of highly charged small cations dissolved in solvents which are strong Lewis bases, such as DMF, DMSO, or organic phosphates. Hence, for aluminum cations, a large number of studies have been performed where complexation to such high donicity solvents has been investigated in detail. Most studies have been conducted using the perchlorate salt, since its hexasolvate is relatively easily prepared. In neat DMSO solution, separate ¹³C NMR signals are observed for both bulk and bound solvent (i.e. the hexa-DMSO solvate) at temperatures up to 40°C, where the signals broaden. This system has been carefully analyzed by stopped-flow proton spectroscopy, where changes in signal intensities have been monitored as solvent exchange occurs between bound and bulk states in nitromethane diluent. It has been reported that the rate of exchange is independent of DMSO concentration, as expected for a dissociative mechanism.

The complexation to DMF has been studied in a similar fashion to give proton signals from both bulk and bound solvent at temperatures as high as 95°C. The coordination number is always six, whatever salt is used, and the large chemical shift change observed for the formyl protons indicates, as expected, that DMF is coordinated via oxygen. If aluminum chloride is dissolved in nitromethane and titrated with small amounts of DMF, then a variety of octahedral and tetrahedral complexes will be formed, for example $\text{AlCl}(\text{DMF})_5^{2+}$ which has a chemical shift of 5 ppm to high frequency of the hexasolvate.

Since ligand exchange rate is slow in both DMSO and DMF, then if a perchlorate salt is dissolved in a binary mixed solvent system one would be able to detect all seven possible solvates by aluminum spectroscopy. Such a study has indeed produced seven rather narrow lines, and the relative intensities could be used to derive the stepwise equilibrium constants which were then compared with the results from the Covington model of preferential solvation.³⁰ Without any added diluent, the overall equilibrium constant, $K^{1/6}$, is equal to 4.5, indicating preferential solvation by DMSO over DMF, which is consistent with the higher donicity number for DMSO (29.8) versus that of DMF (26.6). Addition of an inert solvent such as nitromethane or acetonitrile shows two profound effects on the NMR spectrum. First, there is a clear change in the distribution of peak intensities upon dilution, in which the preferential solvation by DMSO is decreased, i.e. $K^{1/6}$ approaches unity. Secondly, a line narrowing is observed for all lines, irrespective of the actual symmetry. This is another indication that the interaction occurs through the same type of bonding (namely oxygen) for both ligands and that they are roughly indistinguishable to the aluminum core as far as EFG is concerned. The chemical shift parameter is by far a more sensitive probe in this respect.

Aluminum perchlorate has also been studied recently in aqueous mixtures of DMF and urea and it was found that Al(III) is hexacoordinated in both aqueous mixtures over the concentration ranges studied.³¹ Although both organic ligands displace water from the first coordination sphere, there is a marked difference between their complexation ability, although they both show monodentate binding to the oxygen atom. The preferential solvation of Al(III) by DMF is particularly evident at the lower concentrations of this ligand, where most of the DMF is complexed at the expense of water.³² This preferred solvation persists up to 1:1 mole ratios of DMF to water, where water then becomes the ligand of choice. In fact, even at DMF concentrations as high as 5:1, water still makes a substantial contribution to the metal coordination shell. This strongly implies that steric interactions play an important role in the binding of these ligands, hindering the formation of higher DMF complexes.

These steric effects are not so obvious for the urea ligands. Hence, urea essentially selectively solvates Al(III) in aqueous mixtures, almost to the complete exclusion of water. The preferential solvation tendency of urea is increased if the bulk solvent contains increasing amounts of the relatively inert solvent acetone. In 50:1 acetone–water, a bound water signal could not be detected at a mole ratio of 6:1 urea to Al(III).

As far as organic phosphates and related compounds are concerned, this group of solvents form well-defined stable solvates via the P=O oxygen atom. They are of a particular interest to NMR spectroscopists since they provide examples of structurally useful spin–spin coupling to aluminum.

In DMMP [$\text{Me}(\text{MeO})_2\text{PO}$], TMPA [$(\text{MeO})_3\text{PO}$], and similar phosphates, octahedral complexes are formed, as shown by a well-defined septet aluminum resonance from the spin–spin coupling to six phosphorus atoms. The exchange data are generally consistent with a dissociative mechanism and the perchlorate salt of the DMMP hexasolvate exhibits much faster exchange than TMPA (at 25°C, $k = 5.1 \text{ s}^{-1}$ and $k = 0.4 \text{ s}^{-1}$ respectively).

HMPA, on the other hand, shows a different behavior. Although being one of the best donating (and, unfortunately,

most carcinogenic) solvents, it only forms a tetracoordinated complex, presumably due to steric reasons. The ^{27}Al resonance is consequently only a quintet. The coupling constant increases, as consistent with an increase in the s character in the bonding. The exchange rate also becomes faster and is proportional to the concentration of free HMPA. The enthalpy of activation is reduced and the entropy of activation is negative, all consistent with an associative mechanism of exchange for this HMPA complex.

5.2 Aluminum(III) Complexation in Alcohols

Alcohols are relatively strong donors to Al(III) , but are more easily displaced by water molecules than the solvents mentioned in the preceding section. If completely anhydrous, alcohols do not displace chloride from AlCl_3 entirely, a tendency which seems to be more apparent with increasing length of the alkyl chain.

The current understanding of solutions of AlCl_3 or $\text{Al}(\text{ClO}_4)_3$ in carefully dried methanol is based on high-field ^{27}Al NMR experiments, and these studies show, in the case of AlCl_3 , three resonances at 13.15, 9.55, and 3.45 ppm. The major peak at 9.55 is suggested to be $\text{AlCl}_2(\text{MeOH})_4^+$, and this peak decreases if the perchlorate is used. The peak at 3.45 ppm then dominates. The broad low-frequency peak, close in shift to the hexahydrate, is argued to be due to exchange between the MeOH pentasolvate and the hexasolvate. Finally, the high-frequency resonance is then assigned to $\text{AlCl}_3 \cdot 3\text{MeOH}$. If higher alcohols are used, the signals will become broader, although ethanol seems to behave differently. At high dilution in CDCl_3 , there is ample evidence of a hexasolvate complex appearing as a weak narrow peak at 3 ppm. A recent MAS study of anhydrous ethanolic solutions yielded similar complexes and shifts to those reported for methanol solutions using high-resolution NMR.³³

5.3 Hydridoaluminates in Organic Solvents

Reducing agents such as various hydridoaluminates have been studied frequently in a variety of organic solvents in an attempt to understand ion-pairing effects, hydride exchange, etc. The scalar coupling between aluminum and hydrogen is sufficiently large (ca. 174 Hz for AlH_4^-) for it to be observed for a wide range of aluminum relaxation times. In THF, the linewidths change only slightly with concentration or temperature. In monoglyme, the coupling pattern is only seen at concentrations below 1 M, while in diglyme the opposite effect is noticed. In the latter case, the linewidths are quite narrow at high concentrations, but increase upon dilution.

Alkoxyaluminates, formed by the reaction between LiAlH_4 and alcohols, are also important species since they can serve as useful selective reducing agents. Many attempts have been made to design chiral complex metal hydrides, such as complexes with LiAlH_4 and chiral alcohols, for asymmetric reduction of prochiral carbonyl compounds. However, disproportionation equilibria take place with many primary, secondary, and tertiary alcohols, which of course is a limiting factor for the success of asymmetric reduction.³⁴ Addition of various chiral amino alcohols to LiAlH_4 in THF or diglyme has been studied by aluminum NMR, and disproportionation reactions have been found to vary with the structure of the amino

alcohol. The small and flexible (–)-*N*-methylephedrine causes disproportionation to a significant degree, the bulkier and more rigid (–)-quinine less so.³⁵ The tridentate alcohol (–)-(*S*)-4-anilino-3-methylaminobutan-1-ol forms a bicyclic complex with the reagent without production of any measurable amount of free LiAlH_4 . These results are consistent with the order of effectiveness of these reagents as asymmetric reducing agents, confirming that disproportionation equilibria have to be taken into account when designing useful asymmetric reduction experiments. Contrary to Li^+ and Na^+ , tetrabutylammonium alkoxyhydridoaluminates are selective reducing agents in which the catalysis of the ligand exchange and consequent disproportionation are strongly suppressed.³⁶ It was shown that very high stereoselectivity, proportional to the steric strain, could be obtained for bulky alkoxy ligands, high temperatures, and polar solvents. Under these conditions, disproportionation is practically absent during the reduction process.

1 INTRODUCTION

Boron NMR is a term that is often used to encompass a range of techniques which use the properties of boron nuclei to assist in the elucidation of structures and/or dynamics of solutions of boron-containing molecules. When such species are studied it is common practice to obtain NMR spectra of other nuclei in addition to boron, with the results being combined to give a more complete picture of the system under investigation. The main properties of the boron nuclei (namely ^{10}B and ^{11}B) are presented in Table 1, with those of some other nuclei for comparison.

The data in Table 1 indicate why ^{11}B is often preferred to ^{10}B as a nucleus of study, with the main reasons being: (i) boron-11 is considerably more sensitive than boron-10, due to both its greater natural abundance and its greater magnetogyric ratio, γ ; (ii) boron-11 has a greater dispersion, in terms of Hz/ppm, than boron-10; and (iii) coupling constants to ^{11}B are three times greater than to ^{10}B , i.e., $^nJ(^{11}\text{B},\text{X}) = 3 \times ^nJ(^{10}\text{B},\text{X})$. Both ^{11}B and ^{10}B are quadrupolar nuclei ($I = \frac{3}{2}$ and 3, respectively) and the quadrupolar relaxation mechanism is often the dominant one of these nuclei. Consequently, T_1 values for the boron nuclei are often quite short, typically in the range 10^{-2} s to 10^{-3} s for ^{11}B , though if the boron is in a particularly symmetrical environment (e.g. in $[\text{BH}_4^-]$, where the boron is tetrahedrally coordinated by four equivalent ligands), then the T_1 value can be of the order of seconds.

This article will try to show how boron NMR, predominantly ^{11}B and ^1H , can be used to assist in the study of boron chemistry. It will not be a list of data, but will try to show how NMR techniques have been applied in this area and will be confined to the use of boron NMR in the solution state.

2 NMR OF BORON COMPOUNDS, EXCEPT POLYHEDRAL BORANES

Boron chemistry covers a wide subject area, incorporating such diverse topics as, for example, boron oxides, boron halides, organoboron compounds, and polyhedral boranes.¹ The use of boron NMR in some of these areas is limited. Thus, boron oxides often produce very broad and ill-defined ^{11}B

NMR signals with few, if any, additional NMR experiments possible to assist in the analysis of such systems.

The chemistries of the organoboron compounds, boron halides, and mixed systems containing organo-, halo-, and/or other heteroatom groups often involve a single boron atom surrounded by three or four ligands, trigonally or tetrahedrally, respectively. Table 2 shows some ^{11}B NMR chemical shift data for a selection of compounds of this type.² Throughout this article, $\delta(^{11}\text{B})$ values will be quoted relative to that of $[\text{BF}_3\cdot\text{OEt}_2] = 0$.

The table highlights a number of points, the most important of these being: (i) boron-11 chemical shifts vary significantly with the coordination number of the boron (3 or 4); and (ii) the shifts vary significantly with the nature of the ligands.

A semiintuitive rationale for such behavior is provided by considering the nuclear screening constant, σ , which is thought of as being made up of a number of components, i.e. $\sigma = \sigma_d + \sigma_p + \text{others}$, where σ_d is the so-called 'diamagnetic' component and σ_p the 'paramagnetic' component of the screening constant. The others are, for example, neighboring anisotropy effects, ring current effects, electric field effects, etc.

The value of σ_d for nuclei arises as a result of the effects of the external magnetic field on the motion of electrons associated with the nucleus, which causes a secondary magnetic field about the nucleus opposed to the external field. Consequently, the nucleus is shielded from the external field. Hence, any reduction in the electron density about the nucleus will result in the deshielding of the nucleus (for example, as a result of nearby electronegative atoms).

The paramagnetic term, σ_p , can be thought of as arising from a hindrance to the motion of electrons about a nucleus as a result of other electrons and nuclei in the molecule. In the case of the simple boron compounds, σ_p depends on both $1/r^3$ for the valence electrons and their orbital angular momentum. It is of opposite sign to the diamagnetic term and is of greater magnitude.

For tetrahedrally coordinated boron, the significance of the above is that there are limitations on how the paramagnetic contribution to the shielding term can arise. Four-coordinate boron must be sp^3 hybridized, meaning that there are no orbitals available for the acceptance of π electrons from potential π -donor ligands. Also, there are only likely to be minor variations in the orbital angular momentum contributions, as deviations from tetrahedral symmetry will not be significant. Consequently, the major contribution to the nuclear screening constant in the four-coordinate boron systems is the degree of covalency between the ligand and boron.

The situation is rather different for trigonally coordinate boron systems (BR_3 , BX_3 , etc.) in which the boron can be regarded as sp^2 hybridized, with a p orbital available for interaction with π -donor ligands. This leads to a significant variation in orbital angular momentum at three-coordinate boron arising from using ligands of differing π -donor strength, and hence a generally greater range of chemical shifts.

The above points may be most easily understood by considering some examples. Thus, comparing like-for-like trigonal and tetrahedral coordinate boron systems [e.g. BF_3 vs. $[\text{BF}_4^-]$, BCl_3 vs. $[\text{BCl}_4^-]$, BR_3 vs. $[\text{BR}_4^-]$ ($\text{R} = \text{alkyl}$), etc.], it is clear that $\delta(^{11}\text{B})$, trigonal) is to high frequency of

Table 1 Comparison of Some Physical Properties of Boron Nuclei with Other Common Nuclei

Isotope	Natural Abundance (%)	Nuclear spin, <i>I</i>	Magnetogyric ratio, γ	Resonance frequency (MHz) at 2.35 T	Relative sensitivity ($^1\text{H} = 1.00$)
^{10}B	19.58	3	2.875	9.3	3.9×10^{-3}
^{11}B	80.42	$\frac{3}{2}$	8.584	32.1	1.33×10^{-1}
^{13}C	1.108	$\frac{1}{2}$	6.728	25.2	1.76×10^{-1}
^{31}P	100	$\frac{1}{2}$	10.841	40.5	0.66×10^{-1}
^{19}F	100	$\frac{1}{2}$	25.181	94.1	0.83
^1H	99.98	$\frac{1}{2}$	26.752	100.0	1.00

$\delta(^{11}\text{B})$, tetrahedral), with the trigonal systems showing a greater range of $\delta(^{11}\text{B})$ values.

Comparison of the effects of different ligands on the $\delta(^{11}\text{B})$ values of trigonal boron systems, for example $\text{B}(\text{CH}_3)_3$, $\text{B}(\text{OCH}_3)_3$, $\text{B}(\text{NR}_2)_3$, and BF_3 , reveals that the B–C system is at the highest frequency, followed by the B–N, B–O, and B–F systems respectively. This is consistent with the π -donor capability of the ligating atoms. Thus, $\text{B}(\text{CH}_3)_3$ has sp^3 hybridized carbon bound to the boron and this does not have any π -donor capability to provide any additional shielding to the boron, whereas F will have considerable p– π overlap with the boron in BF_3 , resulting in a more shielded ^{11}B environment.

Heavier ligating atoms introduce additional difficulties. For example, examination of the series BF_3 , BCl_3 , BBr_3 , and BI_3 shows that $\delta(^{11}\text{B})$ goes to increasing frequency with the series $\text{F} < \text{Cl} < \text{Br}$. In contrast, BI_3 has the lowest frequency $\delta(^{11}\text{B})$ value of any trigonal boron compound. The results of the F, Cl, Br series can be explained by the decreasing overlap between the ligand p orbitals and the p orbital on the boron, as a result of the increased size of the ligand p orbital with increasing atomic number. The iodo compound is less readily explained, though if a series of mixed organohalo boron chemical shifts

are charted (Figure 1), then it becomes clear that the unusual iodo chemical shifts only occur beyond monosubstitution.

The effects of different ligands on chemical shifts of tetrahedrally coordinated boron, with the exception of the iodo derivatives, are much smaller than those observed for trigonally coordinated compounds, in keeping with the reduced σ_p component to the nuclear shielding constant.

2.1 The Use of Other Nuclei

In addition to ^{11}B NMR data, in many cases it is also possible to look at NMR spectra from other nuclei to assist in establishing the nature of the compounds. Thus in the case of organoboron systems, standard ^1H and ^{13}C NMR experiments could be used to establish the nature of the organic ligands. Clearly, the data thus obtained may not be free of the influence of the boron, as can be seen in the ^1H and ^{13}C NMR spectra of the anion $[\text{BPh}_4^-]$, shown in Figures 2 and 3. The figure captions indicate where the areas of interest lie. The spectra shown here have very clearly defined couplings because of the very symmetrical nature of the molecule, though a tetrahedrally coordinate species which did not have four equivalent ligands around the boron would be unlikely to show such clearly defined couplings as the ^{11}B relaxation would be

**Figure 1** Chemical shift chart for some organo-, halo-, and mixed organohaloboron compounds

Table 2 Chemical Shift Data for a Series of Trigonal and Tetrahedrally Coordinated Boron Compounds

Trigonal		Tetrahedral	
Compound	δ (ppm)	Compound	δ (ppm)
BR ₃	80–90	[BR ₄ [−]]	−16 to −20

more efficient. In the case of the haloboranes, only ¹⁹F is of any significance, with chlorine, bromine, and iodine nuclei all being quadrupolar and exhibiting such rapid relaxation that they are effectively not observable, either directly or indirectly (via *J* coupling).

3 NMR OF POLYHEDRAL BORANES

It is in the study of polyhedral boranes and related compounds that the most extensive use of boron NMR has

been made, with particular emphasis in establishing B–B and B–H connectivities. The problems implicit in carrying out NMR analyses on borane systems lie in the quadrupolar nature of the boron nucleus ¹¹B. This results in many potentially useful parameters being difficult, or impossible, to measure directly. For example, with the exception of ¹J(¹¹B, ¹H), coupling constants are usually totally obscured within the linewidth of an ¹¹B NMR signal. This arises because coupling constants are often quite small [e.g. ¹J(¹¹B, ¹B) values are usually in the range 10–60 Hz, and ¹J values between ¹¹B and bridging ¹H nuclei are often of the order of 40 Hz], the natural linewidth of the signal may be quite large (≥10 Hz) and there may be several couplings associated to any given ¹¹B signal. The situation obtained in ¹H NMR spectra of such compounds is not any clearer.

To illustrate these points, let us consider the ¹¹B, ¹¹B{¹H}, ¹H, and ¹H{¹¹B} NMR spectra of a ‘typical’ borane, the anion [B₁₀H₁₁Se[−]]³ (Figures 4 and 5). The ¹¹B and ¹¹B{¹H} data in this case give some indication of the degree of symmetry of the anion, though such interpretations have to be treated with caution as ¹¹B signal overlap is not uncommon. Furthermore, it is clear that these spectra only permit $\delta(^{11}\text{B})$ and ¹J(¹¹B, ¹H) data to be extracted [though occasionally other parameters may be measured directly, e.g. ¹J(¹¹B, ¹¹B)]. The fully coupled ¹H NMR spectra of boranes are very complex [Figure 5(a)] due to the following:

1. The $\delta(^1\text{H})$ range is often quite small, from δ 0.0–4.0 ppm for resonances arising from *exo*-polyhedral terminal ¹H nuclei.
2. Each resonance will have at least four lines of equal intensity arising from coupling to ¹¹B (*I* = $\frac{3}{2}$), with ¹J(¹¹B, ¹H) being typically in the range 120–160 Hz.
3. The lines are often very broad (≥10 Hz is not uncommon).

These factors result in ¹H spectra which are comprised of many overlapping 1:1:1:1 multiplets over a relatively narrow δ range. Signals arising from bridging protons (either B–H–B or B–H–M) are found at much lower δ values, normally several ppm to low frequency of TMS. In these cases ¹J(¹¹B, ¹H)

Figure 2 The 360.13 MHz ¹H (bottom) and ¹H{¹¹B} (top) NMR spectra of the [BPh₄[−]] anion. Note only the signals arising from the protons *ortho* to the boron show any significant coupling to ¹¹B

Figure 3 The 90.56 MHz $^{13}\text{C}\{^1\text{H}\}$ NMR spectrum of $[\text{BPh}_4]^-$. Insets show the effects of coupling to boron on the *ipso* carbon, and on the carbon *meta* to boron. The signal due to the *ipso* carbon ($\delta = 163.4$ ppm) shows four lines of equal intensity, due to a $^1J(^{11}\text{B}, ^{13}\text{C}) = 49.8$ Hz. Seven smaller lines are also observed, due to $^1J(^{10}\text{B}, ^{13}\text{C}) = 16.6$ Hz. By use of resolution enhancement, the $^3J(^{11}\text{B}, ^{13}\text{C})$ coupling between the boron and the *meta* carbons is measured at 2.3 Hz

Figure 4 The 192.5 MHz ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ NMR spectra of the $[\text{B}_{10}\text{H}_{11}\text{Se}]^-$ anion, whose structure is shown as an inset

Figure 5 The 600 MHz ^1H (a), $^1\text{H}\{^{11}\text{B}\}$ (b) and difference spectrum (c) of $[\text{B}_{10}\text{H}_{11}\text{Se}^-]$

values are smaller than those observed for terminal *exo*-polyhedral sites, often being in the range 30–50 Hz, with the ^1H displaying coupling to two ^{11}B nuclei to give a 1:2:3:4:3:2:1 multiplet.

The ^1H spectra can be greatly simplified by broadband ^{11}B decoupling, with the results of this type of experiment being shown in Figure 5(b) for $[\text{B}_{10}\text{H}_{11}\text{Se}^-]$. This, while being much simpler than the fully coupled spectrum, is still a little unclear because of the large signals due to protons in the counterion $[\text{NEt}_3\text{H}^+]$. This type of complication is often overcome by presenting the data as a difference spectrum [see Figure 5(c)].

As mentioned earlier, for both ^{11}B and ^1H spectra of borane derivatives, signal overlap is a common problem, and as a result NMR studies of such materials often benefit from the use of higher magnetic fields. The compound $[\text{B}_9\text{H}_9\text{Se}_2]$ provides an example of an $^{11}\text{B}\{^1\text{H}\}$ spectrum with considerable overlapping of signals, and Figure 6 shows how this spectrum varies with increasing field strength.

3.1 Experimental Techniques

The previous section showed how only limited information can be extracted from ^{11}B , $^{11}\text{B}\{^1\text{H}\}$, ^1H , and $^1\text{H}\{^{11}\text{B}\}$ spectra of ‘unknown’ borane derivatives. To try to establish required

information, it is most common to use methods of homonuclear ($^{11}\text{B}/^{11}\text{B}$ and $^1\text{H}/^1\text{H}$) and heteronuclear ($^{11}\text{B}/^1\text{H}$) correlation, as appropriate.

Heteronuclear $^{11}\text{B}/^1\text{H}$ correlation can be carried out either two-dimensionally, using the so-called HETCOR sequence,⁴ or one-dimensionally by carrying out a series of selective $^1\text{H}\{^{11}\text{B}\}$ experiments. Historically, the first demonstration of the application of two-dimensional (2D) NMR to boron chemistry was shown using the HETCOR sequence, and was applied to the carborane $\text{C}_2\text{B}_5\text{H}_7$,⁵ followed by two papers showing $^{11}\text{B}/^1\text{H}$ correlation spectra of decaborane(14), $\text{B}_{10}\text{H}_{14}$.^{6,7} The standard HETCOR sequence (Figure 7) uses delays, indicated in the figure, which are responsible for the transfer of magnetization between ^1H and ^{11}B , and are equal to $0.5/{}^1J(^{11}\text{B},^1\text{H})$.

This leads to problems where the values of the coupling constants are quite different, e.g. between *exo*-polyhedral B–H terminal environments and B–H–B bridging sites (typical coupling are ca. 140 Hz and 40 Hz, respectively). In these cases it may be necessary to perform two experiments using delays derived from the different J values.

An alternative, and often more popular, way of achieving effective $^{11}\text{B}/^1\text{H}$ correlation is by ^1H observation with selective, low power, ^{11}B decoupling. Such data are usually

Figure 6 The effect of increasing field strength illustrated by the $^{11}\text{B}\{^1\text{H}\}$ NMR spectra of $[\text{B}_9\text{H}_9\text{Se}_2]$ obtained at 64.2 MHz (top), 115.5 MHz (center), and 192.5 MHz (bottom)

presented as a series of decoupling difference spectra. This type of experiment is performed by acquiring ^1H spectra whilst simultaneously irradiating at the resonance frequency of each individual ^{11}B site in turn. A spectrum obtained by applying decoupler power at an ^{11}B off-resonance position is also obtained. By subtracting the off-resonance decoupled spectrum from the selectively irradiated spectra in turn, a series of difference spectra are produced.

Homonuclear $^{11}\text{B}/^{11}\text{B}$ correlation experiments are performed using the simplest of the various 2D COSY sequences (Figure 8). The first demonstrations of the use of this type of experiment to boron chemistry were published in 1982.⁸ Subsequent work widened the range of borane derivatives studied and from these experiments conclusions have been drawn as to the applicability of COSY to such clusters, along with some limitations,^{9,10} these being: (i) no cross peaks have been observed between nonadjacent ^{11}B nuclei; (ii) boron nuclei linked by bridging hydrogen atoms are less likely to show cross peaks, though such peaks can be found in some cases. (iii) boron-11 relaxation can be very efficient, and where $1/T_1 \leq 2\pi J$, i.e. for very broad signals, useful data may be impossible to obtain; (iv) where signal overlap occurs, interpretation may be a problem; and (v) expected cross peaks do not always show up.

Very often a combination of $^{11}\text{B}/^{11}\text{B}$ and $^{11}\text{B}/^1\text{H}$ correlation experiments proves to be enough to resolve the structure of a cluster. However, sometimes additional information is needed, and may be provided by homonuclear $^1\text{H}/^1\text{H}$ correlation experiments. As with the $^{11}\text{B}/^{11}\text{B}$ experiments, the simplest of the COSY sequences is used. Although ^1H COSY has been widely used for organic molecules since the introduction of 2D NMR in 1976,^{11,12} it was not until 1986 that its application to borane clusters was first shown,¹³ presumably partly as a result of the difficulties in achieving effective ^{11}B decoupling.

Because of the relatively rapid ^1H relaxation, it is $^3J(^1\text{H}, ^1\text{H})$ couplings that are the most likely to be observed this way. Thus it should be possible to observe cross peaks between ^1H nuclei on adjacent cluster positions. This is potentially useful for the following reasons: (a) if an expected cross peak between adjacent boron nuclei is not observed, it may be that the $^1\text{H}/^1\text{H}$ cross peaks could establish the connectivity; and (b) in carboranes, if a CH moiety is adjacent to BH moieties in the cluster, then B–C connectivities can be established.

3.2 Case Studies

To establish the effectiveness of the techniques described in the previous section, three case studies will be outlined to illustrate them.

3.2.1 Case Study 1

The objective was the complete assignment of the ^{11}B and ^1H spectra of the anion $[\text{B}_{10}\text{H}_{11}\text{Se}^-]$, these being shown earlier in Figures 4 and 5. This was achieved by a combination of selective $^1\text{H}\{^{11}\text{B}\}$ experiments and an ^{11}B COSY experiment.

The structure of the anion (see Figure 4), which had been determined X-ray crystallographically, showed a plane of symmetry through positions 1, 5, and 7 in the cluster. This meant that the ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ spectra should show six distinct boron environments, four of area 2 and two of area 1 (as shown in Figure 4). Equally, the $^1\text{H}\{^{11}\text{B}\}$ spectrum should show six signals arising from *exo*-terminal hydrogens, and a signal due to a bridging hydrogen, these being clearly shown in Figure 5(c).

A series of selective $^1\text{H}\{^{11}\text{B}\}$ results are presented in Figure 9 as difference spectra, along with an $^{11}\text{B}\{^1\text{H}\}$ spectrum showing the irradiation sites labeled A–F. Each ^{11}B signal is correlated with a signal deriving from a terminal *exo*-hydrogen,

Figure 7 The HETCOR sequence as often used in ^{11}B – ^1H correlation experiments. The delay periods D3 and D4 are set by taking $\text{D3} = 0.5/J(^{11}\text{B}, ^1\text{H})$ and either $\text{D4} = \text{D3}$ or $\text{D4} = 0.25/J(^{11}\text{B}, ^1\text{H})$. Relaxation delays of 1.0 s to 2.0 s are not uncommon

with ^{11}B signal E also correlating with the bridging hydrogen signal. Hence signal E derives from B (9,10).

The ^{11}B COSY experiment (Figure 10) permits full assignment, with two major starting points.

Phase cycles

Pulse A : $(x)_4 (y)_4 (-x)_4 (-y)_4$

Pulse B : $(x) (-x) (y) (-y) (y) (-y) (-x) (x)$
 $(y) (-y) (-x) (x) (-x) (x) (-y) (y)$

Receiver : $(x) (x) (-x) (-x) (y) (y) (-y) (-y)$

Figure 8 The COSY sequence as used in both homonuclear ^{11}B and ^1H correlation experiments. Note that the ^1H decoupling used in ^{11}B COSY experiments can be applied as indicated or throughout the entire experiment. For ^1H COSY experiments, the ^{11}B decoupling is usually applied as indicated to minimize sample heating

1. B(9,10) give signal E. This shares a cross peak with C which has relative area 1, hence C must arise from B(5) and F (also area 1) must derive from B(1).
2. Signal A couples to all the others and must be due to B (4,6).

This leaves only signals B and D unassigned. Signal B shares a cross peak with E, and must be due to B(8,11), leaving signal D as B(2,3). It is notable that an expected cross peak between B and D is missing. Table 3 summarizes these results.

3.2.2 Case Study 2

This involved distinguishing between two possible structures for $[\text{B}_9\text{H}_9\text{Se}_2]^-$,¹⁴ these being shown in Figure 11 along with its ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ spectra. Both of the proposed structures possess a plane of symmetry through cluster positions 1, 3, and 10, and hence would be expected to give six resonance

Table 3 Assignments of ^{11}B and ^1H Spectra of $[\text{B}_{10}\text{H}_{11}\text{Se}^-]$

B–H site	$\delta(^{11}\text{B})$	$\delta(^1\text{H})$
8, 11	–9.2	2.05
2, 3	–16.3	1.67
9, 10	–17.6	1.26
		(also $\mu\text{-H}$, –4.11)
4, 6	–5.6	2.37
1	–35.6	1.05
5	–14.6	1.83

Figure 9 A series of 600 MHz selective $^1\text{H}\{^{11}\text{B}\}$ NMR difference spectra of $[\text{B}_{10}\text{H}_{11}\text{Se}^-]$, with an $^{11}\text{B}\{^1\text{H}\}$ spectrum indicating the irradiation positions

positions in the ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ spectra, three of area 2 and three of area 1. As we saw earlier, (Figure 6) only the highest field spectra can show this unambiguously.

The solution to this problem is obtained from the ^{11}B COSY experiment (Figure 12), using the premise that only adjacent ^{11}B nuclei give rise to 2D cross peaks.

If the correct structure were structure I, then B(1), B(3) and B(10) should display three, three, and one cross peak, respectively. If the structure were II, with adjacent selenium atoms, then B(1), B(3), and B(10) would show three, two and two cross peaks, respectively. The COSY plot shows signals A and F have three cross peaks each, with E having one cross peak. Hence I is the correct structure.

It is also possible to complete a full assignment of the ^{11}B spectrum by noting that E must derive from B(10), and couples to D which must be due to B(5,6). Signal D also couples with F but not A, so F arises from B(1) and A from B(3). There is an F/B cross peak but not an F/C one, so B derives from B(2,4) and C from B(7,8).

Again there were cross peaks missing which were expected, namely B/C and B/D.

3.2.3 Case Study 3

Here, as in case study 1, the question was one of assignment, this being for the molecule $[1\text{-Ph-1,2-}\text{C}_2\text{B}_{10}\text{H}_{11}]$, the structure

of which is shown in Figure 13, along with its ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ NMR spectra.¹⁵

The spectra are consistent with the structure, comprising six signals (labeled A–F) of relative intensities 1:1:2:2:2:2, respectively. The $^1\text{H}\{^{11}\text{B}\}$ spectrum [Figure 14(a)] showed six peaks of relative intensities 1:2:2:1:3:2, labeled I–VI respectively, arising from cage hydrogen atoms, with signals due to phenyl protons showing in the range δ 7.0–8.0 ppm. Comparison with the ^1H spectrum [Figure 14(b)] confirmed signal I as the CH cage proton.

Heteronuclear $^{11}\text{B}/^1\text{H}$ correlations showed the following B/H matches: A/IV, B/V, C/V, D/III, E/II, and F/VI. The homonuclear ^{11}B COSY experiment (Figure 15) showed all the potentially expected cross peaks, but even when combined with the heteronuclear data, unambiguous assignment is not possible. The exception is that ^{11}B signal C must derive from B(8,10), as this signal displays cross peaks to all the others. Complete and unambiguous assignment was obtained with the help of a ^1H COSY experiment (Figure 16).

From this it is clear that signal I couples to signals II and VI, each of which must be either H(3,6) or H(7,11), because these are the H positions most likely to couple to the cage CH. The $^{11}\text{B}/^1\text{H}$ correlation data link II to ^{11}B signal E, and VI to ^{11}B signal F. The ^{11}B COSY shows F couples to B, but E does not couple to any ^{11}B signal of relative area 1. Hence F arises from B(7,11) and E from B(3,6). This means signal B is due to B(12), meaning A derives from B(9). Signal C was

Figure 10 A 192.5 MHz ^{11}B COSY experiment on $[\text{B}_{10}\text{H}_{11}\text{Se}^-]$

already shown to be B(8,10), leaving D as B(4,5). From this, the ^1H assignments can also be made.

3.3 Chemical Shifts

Considerable effort has been invested into devising a rationale for $\delta(^{11}\text{B})$ values in polyhedral borane derivatives over the years, with major advances being made in the understanding of ^{11}B shifts of boranes and main group heteroboranes in particular.¹⁶ In Section 2, a qualitative introduction to the ideas of ^{11}B chemical shift theory was outlined, and these ideas will now be developed to incorporate polyhedral systems.

To appreciate fully the factors involved in the chemical shifts of these systems, it is useful to consider the bonding in them.¹ Boranes are made up of a series of (usually) sp^3 hybridized boron atoms, with one of the orbitals involved in bonding to an *exo*-polyhedral atom (usually H), with the remaining lobes involved in bonding to the cluster. As boron has three valence electrons, and one of these is taken up in the *exo*-polyhedral bond, it means that each boron vertex contributes two electrons to the cluster, giving rise to the so-called electron deficient nature of these systems. In fact, the clusters are considered to be made up of B-H units linked by a series of two- and three-center bonds (i.e. B-B, B-H and BBB, BHB, respectively). This is illustrated in Figure 17, with the bonding situation for B_6H_{10} , hexaborane(10).

Thus we see that whilst each B vertex of the cluster is sp^3 hybridized, it may have more than four nearest neighbors, creating strain on the nominal tetrahedral geometries associated with the boron atoms, and this would affect the shielding about the nuclei and hence influence their chemical shifts. In addition to this, the electron delocalization about such clusters would produce ring current effects (analogous to those found

Figure 11 The ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ NMR spectra of $[\text{B}_9\text{H}_9\text{Se}_2]$ obtained at 192.5 MHz, and its structure

Figure 12 The results of a 192.5 MHz ^{11}B COSY experiment performed on $[\text{B}_9\text{H}_9\text{Se}_2]$

Figure 13 The 192.5 MHz ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ NMR spectra of the closo-carbaborane [1-Ph-1,2- $\text{C}_2\text{B}_{10}\text{H}_{11}$], and an ORTEP diagram of its structure. Note there is a plane of symmetry through C-1, C-2, B(9), and B(12)

in aromatic organic compounds) which would have effects on nuclei nearby. Further potentially significant factors are the presence of other nuclei as cluster vertices (see the case studies for examples of these heteroboranes), and the presence and nature of *exo*-polyhedral atoms other than hydrogen. In particular, not only can substituents influence the boron chemical shift of the atom they are bonded to, but they can also have significant effects on the shifts of certain remote boron nuclei, the TRANS and ANTIPODAL effects.¹⁰

Recently, with the increasing amounts of ^{11}B chemical shift data that are accruing, techniques for calculating chemical shifts are being developed, most notably the IGLO method (Individual Gauge for Localized Orbitals).¹⁷ Good levels of success have been attained on a range of smaller boranes,

borane ions and some *closo* carba- and heteroboranes.¹⁸ These calculations do require precise atomic coordinates, which may be experimentally measured (X-ray crystallography) or calculated (ab initio methods).

3.4 Dynamic Systems

Boron hydrides and their metallo derivatives are often found to exhibit various types of fluxional behavior. In the case of metallo derivatives, this often involves ligands other than the borane moiety, e.g. phosphine rotation, and this type of fluxionality will not be dealt with here. The most common type of fluxional process which is inherent to boranes is bridge

Figure 14 The 600 MHz ¹H{¹¹B} (top) and ¹H (bottom) NMR spectra of [1-Ph-1,2-C₂B₁₀H₁₁]

Figure 15 The 192.5 MHz ¹¹B COSY spectrum of [1-Ph-1,2-C₂B₁₀H₁₁]

Figure 17 The bonding in *nido*-hexaborane(10), $[B_6H_{10}]$

Figure 18 The structures of anions (a) $[B_5H_8^-]$ and (b) $[B_9H_{14}^-]$

hydrogen fluxionality. In some cases, particularly some simple borane anions, the energy barrier to this can be demonstrated to be very low; for example, the ^{11}B NMR data for the anions $[B_5H_8^-]$ and $[B_9H_{14}^-]$ [Figure 18(a) and (b)] are much simpler than might be expected from the structures.^{19,20}

The ^{11}B spectra of $[B_5H_8^-]$ show only two signals of relative intensities 1:4, indicating fluxionality of the bridging hydrogens (μ -H atoms) about the square base. Perhaps even more surprising is the fact that the ^{11}B data on $[B_9H_{14}^-]$ only show three resonances of relative areas 1:1:1. These have been shown to be due to B(4,6,8), B(5,7,9), and B(1,2,3). This has been rationalized as the creation of an effective C_{3v} symmetry arising from fluxionality between the two μ -H atoms and the three *endo* hydrogens nominally located at B(6), B(7), and B(8). For both of these anions, even cooling the system to very low temperature failed to slow down the fluxional process enough to detect the solid state asymmetry with NMR.

The derivatization of $[B_9H_{14}^-]$ to form $[B_9H_{13}L]$ (Figure 19), where L can be one of a large range of neutral or anionic ligands (e.g. Me_2S , NCS^- , etc.), has shown that a considerable reduction in the rate of fluxionality can be effected, though the larger ligand (L instead of H^-) has also affected the solid state structure.^{21,22} A comparison of the fully coupled ^{11}B NMR spectra of $[B_9H_{13}SEt_2]$ and $[B_9H_{13}NCS^-]$ (Figure 20) shows that the nature of L can have a marked effect on the fluxional behavior, with the H on B(4) exhibiting rapid

Figure 19 The structure of $[B_9H_{13}L]$, where L can be one of a range of neutral or anionic ligands (e.g. R_2S , $MeCN$, NCS^- , etc.)

Figure 20 The 115.5 MHz ^{11}B NMR spectra of $[B_9H_{13}SEt_2]$ and $[B_9H_{13}NCS^-]$

exchange with the μ -H atoms and the *endo*-H-6 and H-8 atoms in the anionic case [hence no coupling between H-4 and B(4)] but an effectively static structure being observed for the neutral molecule where the B(4) signal appears as a doublet due to coupling to H-4.

4 FUTURE POSSIBILITIES

Thus far, we have seen that a range of 1D and 2D NMR experiments can greatly assist in the characterization of a variety of different boron compounds. To a large extent the experiments available are limited by the nature of the boron nuclei, in particular their efficient relaxation properties. These problems are mostly found in metallo derivatives, particularly for boron nuclei close to the metals. For 2D experiments (in particular ^{11}B COSY), this means that information resulting from the first pulse (the preparation pulse) vanishes more quickly than for many other (usually spin- $\frac{1}{2}$) nuclei. This can, to some extent, be overcome by either: (i) warming the sample, thereby decreasing the efficiency of the quadrupolar relaxation (this is not always an option as many samples are thermally unstable); or (ii) reducing the value of the incrementation in the variable delay periods in 2D spectra. This has the effect of decreasing the digital resolution because it is accomplished by increasing the spectrum width. For broad lines this is not necessarily a major problem. However if T_1 is too short, effective decoupling will occur between nuclei and cross peaks will not be found.

These factors aside, other 2D experiments will undoubtedly continue to be investigated. Homonuclear TOCSY spectra,²³ which show cross peaks between all nuclei in a given spin system, have recently been obtained on borane clusters (Figure 21) thereby providing a possible means by which multicenter systems can be studied.²⁴

Figure 21 A comparison of a 192.5 MHz ^{11}B TOCSY experiment on [1-Ph-1,2- $\text{C}_2\text{B}_{10}\text{H}_{11}$] with a COSY experiment performed under similar conditions

An additional benefit of the TOCSY experiment is the relative narrowness of the diagonal and cross peaks relative to a COSY spectrum of the same material. This arises because COSY experiments are carried out in the absolute value mode and TOCSY experiments in the phase-sensitive mode.

It is difficult to see how 3D NMR²⁵ could be applied to more than a few isolated cases in boron chemistry because of the extended nature of the 3D pulse sequences and the problems that rapid boron relaxation would introduce as a result.

Finally, it may be that ^{10}B will be utilized more often as a result of increased magnetic field strengths giving both greater signal sensitivity and dispersion. In addition there has been a great deal of investment in the development of boron neutron-capture compounds²⁶ with a view to their eventual use in cancer treatment, and it is ^{10}B that is the active isotope in such studies.

The potential for the application of 2D techniques to ^{10}B is likely to be even more limited than to ^{11}B , because T_1 values of ^{10}B nuclei are similar to equivalently located ^{11}B nuclei but $^nJ(^{10}\text{B},\text{X})$ values are much smaller. Hence the transmission of information from ^{10}B nuclei to other nuclei is not going to be as effective as that from equivalent ^{11}B nuclei.

1 INTRODUCTION

Whilst most people have some idea of what constitutes a metal or a polymer, ‘ceramic’ is a less certain term. Dictionaries define ceramics in terms of pottery and earthenware; however, a more scientific definition is ‘nonmetallic, inorganic materials that are made or used at high temperatures’. The range of ceramics is very broad and covers both very old and very new materials. This article will be mostly concerned with what might be termed advanced structural ceramics, since it is for these materials that NMR has been most useful in characterization and in providing structural information. (The ceramic superconductors are covered in *High Temperature Superconductors*, and will not be discussed here.) These engineering ceramics are typically based on oxides or low-density covalently bonded materials such as silicon nitride or carbide. They are often compositionally complex and, in addition, many ceramics contain atoms of similar X-ray scattering factors such as silicon and aluminum, oxygen and nitrogen, or carbon and nitrogen, so that X-ray scattering techniques are of limited value for obtaining structural information. NMR is a particularly valuable investigative tool for ceramics because it is element- and site-specific. The chemical shift, which is the most often used NMR parameter to obtain structural information in these systems, is most sensitive to the local environment around the atom under investigation, i.e. the nature, number, and position of nearest-neighbor atoms with some sensitivity to the next neighbor shell but very little sensitivity to the structure beyond the fourth coordination sphere. Hence, NMR can be used to characterize poorly crystallized or glassy (see *Amorphous Materials*) samples and to study the formation of the crystalline phase from the amorphous precursor. Many practical ceramics are solid solutions of different compounds and thus, at least in principle, compositionally disordered (i.e. a particular site can be occupied by, say, either a silicon or an aluminum atom); the distinct shifts observed for each ‘local’ configuration are very useful in determining this local order.

2 CERAMICS OF SiC AND Si₃N₄

The sensitivity of NMR to small structural changes in these systems is illustrated by the ²⁹Si, ¹³C, and ¹⁵N shifts of two important ceramic materials, Si₃N₄ (using ¹⁵N-enriched

samples for Si₃N₄) and SiC, given in Table 1. The different polymorphs of Si₃N₄ and polytypes of SiC all have readily distinguishable shifts (except the 6H and 15R polytypes, which differ only slightly in the stacking order). It can be seen that ¹⁵N is a particularly sensitive probe: each nitrogen is bonded to three silicon atoms, [NSi₃], yet the different sites have shifts which cover ~20 ppm in both Si₃N₄ polymorphs compared with only 2.1 ppm for the two silicon sites in α-Si₃N₄.^{1–6}

Because of the differences in spectra of the different polymorphs and polytypes, the phase purity of a particular material (often very important in determining the final product of a reaction) can be readily determined. Figure 1 shows, as an example, the ²⁹Si resonance of two samples of Si₃N₄ which differed only slightly in preparation conditions. Whilst both spectra show two lines indicative of the presence of α-Si₃N₄, in the upper spectrum the lines are of unequal intensity, and careful inspection shows that the right-hand line is slightly shifted from the value expected for pure α-Si₃N₄, indicating that some β-Si₃N₄ is present. The amount can be estimated by subtraction to an accuracy of order 1%, which is difficult to achieve using other techniques. However, one problem with NMR investigations of spin $I = \frac{1}{2}$ nuclei in ceramic materials is their very long spin–lattice relaxation times, T_1 , which can make experiments fairly time-consuming or difficult. Typically, in pure samples, T_1 of ²⁹Si, ¹³C, and ¹⁵N can all be >1000 s, and in fact in one experiment on SiC⁴ no signal was observed even after allowing the sample to polarize in the magnet field for 96 h! For samples with more than one site it is therefore important for quantitative results to make sure that possible differences in T_1 of the different sites have been investigated.

3 OXYNITRIDE CERAMICS

A number of oxynitride ceramics, particularly the ‘sialons’, have practical applications as high-temperature engineering components. The simplest (in the compositional sense) of these ‘sialons’ are those based upon the β-Si₃N₄ structure into which alumina has been substituted. These β’-sialons have the general formula Si_{3–x}Al_xO_xN_{4–x} (0 ≤ x ≤ 2). The ²⁹Si spectrum changes very little with alumina substitution even for x = 2, which seems to indicate that silicon is always surrounded by nitrogen.¹ If this is the case, then aluminum will have a range of tetrahedral AlO_yN_{1–y} (y = 0, . . . ,4)

Figure 1 The ^{29}Si spectrum of two samples of Si_3N_4 . The lower spectrum is pure $\alpha\text{-Si}_3\text{N}_4$, while the upper is from a sample with 79% $\alpha\text{-Si}_3\text{N}_4$ and 21% $\beta\text{-Si}_3\text{N}_4$

environments. In the case of mixed AlON tetrahedra, one can expect there to be a very large electric field gradient (EFG) at the aluminum site; furthermore, because of the different possibilities for the arrangement of the oxygen and nitrogen around the aluminum, there will be several different EFGs associated with each possibility. Thus, very broad ^{27}Al lines are to be expected. In fact in early experiments at 8.45 T it was found that because of the extreme breadth of the line only a small fraction of the ^{27}Al was being observed, the fraction increasing with oxygen content because more AlO_4 tetrahedra which have relatively smaller EFGs are formed.⁷ Later work at 11.7 T using a probe with a short ($\sim 2\ \mu\text{s}$) dead time and fast (16 kHz) spinning was able to observe more of the aluminum present. A broad line from AlO_4 tetrahedra at 68 ppm for $x = 2$ ($\text{SiAl}_2\text{O}_2\text{N}_2$) shifts to ~ 75 ppm, and further broadens as x decreases. The peak at ~ 75 ppm was assigned to AlO_3N .⁸ A small shoulder at 89 ppm, probably from AlO_2N_2 , is also visible for all samples. It should be noted that if the aluminum and silicon were randomly distributed, then AlO_4

Figure 2 Schematic representation of the local structure of β' -sialon with $x = 2$ (i.e. $\text{Si}_{3-x}\text{Al}_x\text{O}_x\text{N}_{4-x}$ or $\text{SiAl}_2\text{O}_2\text{N}_2$). The atoms in columns 1, 4, and 6 are above the plane of the paper, those in column 3 below, with columns 2 and 5 in the plane. The repeat unit along c is between the lines r . x are defects within the layers. (Adapted from Dupree et al.⁷)

would not be dominant even at $x = 2$, and mixed tetrahedra for ^{29}Si would be expected. When combined with the ^{29}Si data the ^{27}Al results strongly indicate a 'microdomain' type of structure in this material. A schematic diagram of this is shown in Figure 2. For small x the thickness of the AlO_4 'block' is reduced, leading to a rapidly increasing amount of mixed AlON tetrahedra.

Many practical oxynitride ceramics require sintering aids in their manufacture, and these react with the SiO_2 found on the surface of the Si_3N_4 grains, forming glassy intergranular phases. Study of these phases and their crystallization products is important in achieving an understanding of the limiting factors which determine the high-temperature properties of these ceramics. One popular aid in sintering is Y_2O_3 , and a number of compounds formed in the Y-Si-Al-O-N have been studied by NMR, as has the crystallization behavior of the glasses formed in this system. Initial measurements on ^{29}Si in this and related systems have determined the shifts of the various compounds, such as $\text{Y}_2\text{SiAlO}_5\text{N}$, YSiO_2N , etc., which are formed and helped to delineate the shift ranges of the $\text{SiO}_x\text{N}_{1-x}$ ($0 \leq x \leq 2$) tetrahedra shown in Figure 3.^{9,10} Note that, as with SiO_4 tetrahedra where there are different numbers of bridging oxygens, there is considerable overlap in the shift range of each local structural unit so that the number of oxygen and nitrogen neighbors cannot be unambiguously determined by the shift position alone. For a proper understanding of the local structure, full multinuclear studies are needed, and ^{15}N on enriched samples has been quite helpful in clarifying several issues. In general, it is found that when nitrogen is coordinated to three silicon atoms, $[\text{NSi}_3]$, the shifts are typically 40–80 ppm, whereas when coordinated to two silicon atoms, $[\text{NSi}_2]$, it resonates in the range 90–160 ppm.⁵ When a glass of the composition

Figure 3 Silicon-29 shift ranges in oxynitrides showing the effect of differing numbers of oxygen neighbors. (Adapted from Dupree et al.¹⁰)

$Y_{1.04}Si_{1.27}Al_{1.27}O_{4.8}N_{0.8}$ was crystallized at $1100^{\circ}C$ the ^{29}Si spectrum showed that six different compounds containing silicon were present including β' -sialon and Si_2N_2O , both of which are also evident in the ^{15}N spectrum. The ^{15}N spectrum also showed a broad peak at ~ 148 ppm and a sharp peak at 285 ppm. The former was shown to be from metastable Y_2SiAlO_5N , where nitrogen coordination would be either $[NSi_2]$ or $[NSiAl]$, by annealing at $1250^{\circ}C$ when both the ^{29}Si signal from this phase and the ^{15}N line at 148 ppm were markedly reduced. The peak at 285 ppm was identified as nitrogen substituted into yttrium aluminum garnet, $Y_3Al_5O_{12}$ (YAG), which is a major phase present. Analysis with TEM-EDAX showed that in the crystalline YAG approximately 14% of the aluminum was replaced by silicon, and it is likely that nitrogen will concurrently substitute for oxygen to maintain charge balance. The shift of this peak is much larger than for $[NSi_2]$ sites, so the most likely local environment is a nitrogen coordinated to a single silicon atom at the tetrahedral site in YAG and a vacancy at the octahedral aluminum site, i.e. $[NSi^*]$.

4 ZIRCONIA CERAMICS

Zirconia (ZrO_2) is an important high-toughness engineering ceramic which in its practical form is usually a mixture of several different crystallographic phases and/or is stabilized by some substituent such as yttrium or magnesium. Neither ^{91}Zr nor ^{17}O (unless enriched) can be regarded as ideal NMR probes, both have spin $I = \frac{5}{2}$, and whilst the natural abundance of ^{91}Zr at 11.2% is enough for NMR experiments (the sensitivity is 2.9 times ^{29}Si) the quadrupole moment is quite large such that in noncubic environments the linewidth is much too great for narrowing techniques such as MAS or DOR to be effective. Oxygen-17 has a much smaller (10^{-2}) quadrupole moment than ^{91}Zr , such that in an ionic environment such as ZrO_2 the EFG is quite small, the quadrupole coupling constant χ ($= e^2qQ/h$) being less than 3 MHz. In this case, despite the natural abundance of ^{17}O being only 0.037%, it is possible (with considerable averaging) to obtain spectra from unenriched materials that clearly distinguish between the tetragonal phase with one oxygen site ($\delta \approx 380$ ppm), the monoclinic phase with two sites ($\delta \approx 325$ and 401 ppm),

and the cubic phase with a broad line at ~ 375 ppm from the disorder due to vacancies in the structure.¹¹ Natural abundance ^{17}O experiments are time-consuming, however, and of limited practicality for day-to-day examination of these materials.

The phases of ZrO_2 zirconium have either seven (orthorhombic and monoclinic) or eight (cubic and tetragonal) oxygen neighbors, and thus the ^{91}Zr chemical shift difference between these phases is likely to be small. However, because of differences in local symmetry the ^{91}Zr EFG and the asymmetry parameter, η , are likely to be very different, and thus the phases can be distinguished by their quadrupolar lineshapes. The very large linewidth (~ 500 kHz in a 9.4 T field) means that the spectrum is best acquired on a static sample point by point. An advantage of a static NMR experiment is that the sample does not have to be powdered, which on this type of material may change the relative phase content via the phase transformation (tetragonal $\rightarrow$ monoclinic, tetragonal $\rightarrow$ orthorhombic). The spectra of cubic, monoclinic, and a fired, partially stabilized zirconia (PSZ), acquired at 25 kHz intervals using a spin echo sequence, are shown in Figure 4.¹² In the cubic phase (which contains ~ 13.5 mol% MgO for stabilization) the presence of

Figure 4 The ^{91}Zr spectra of several forms of ZrO_2 . (a) Magnesia-stabilized cubic zirconia (13.5 mol% MgO), (b) monoclinic ZrO_2 , and (c) tetragonal ZrO_2 (MS grade MgPSZ). The minor peaks are from residual monoclinic (m) and cubic (c) phases. (Adopted from Bastow et al.¹²)

oxygen vacancies, needed for charge balance, means that there will be a distribution of quadrupolar coupling constants; thus, a broad featureless line is observed and any structure is lost. The monoclinic phase is well fitted by a line with $\chi = 23.1$ MHz and $\eta = 0.1$, whilst the spectrum of MS grade PSZ is narrower ($\chi = 19.1$ MHz, $\eta = 0$), showing that it is mostly tetragonal with some monoclinic and cubic phase material present.

1 INTRODUCTION

The NMR spectra of enantiomers are fundamentally identical. This is because the projection of magnetic properties along the magnetic field axis is independent of the “handedness” of the molecules. An other way to tell this is to recall that enantiotopic nuclei are isochronous and consequently two objects that are mirror images cannot be differentiated. On the contrary, diastereomers may be distinguished because diastereotopic nuclei are non equivalent. The determination of enantiomeric purity using NMR therefore requires the use of a chiral auxiliary that, in one way or another, converts the mixture of enantiomers into a mixture of diastereomers. Whenever the induced chemical shift inequivalence is large enough to produce well resolved lines, then integration gives a direct measure of the diastereomeric composition which can be easily related to the enantiomeric composition of the original mixture.

Since the late sixties, three types of chiral auxiliaries have been commonly in use in classical NMR in the liquid state. Chiral Lanthanide Shift Reagents¹ and Chiral Solvating Agents² form diastereomeric complexes with substrate enantiomers and may be used directly. Chiral Derivatizing Agents³ require the synthesis of discrete diastereomers prior to NMR analysis. These techniques and their limitations have been nicely reviewed recently by David Parker.⁴

In this contribution we describe a more recent technique which proceeds through the use of chiral liquid crystals as the NMR solvent. Here the chiral discrimination originates in a

difference of the enantiomer ordering when dissolved in such a medium. Consequently, all order sensitive NMR interactions are different, namely chemical shift anisotropies, dipolar coupling and quadrupolar splitting. The major advantage of this later method is that it works with all types of chiral molecules, independently of any functional group, as in alkanes for instance. Furthermore, this method has been shown to work amazingly well for molecules whose chirality arises by virtue of isotopic substitution. Finally, this technique has been shown to give interesting results in the study of diastereomers with remote asymmetric centres.

2 HISTORY

The idea of using chiral liquid crystal solvents to distinguish enantiomers emerged in the sixties, shortly after the discovery by Saupe and Englert of the usefulness of nematic liquid crystals as anisotropic NMR solvents.⁵ The response of a cholesteric phase to an external homogeneous magnetic field has been studied by McColl et al.⁶ It depends on the sign of the anisotropic magnetic susceptibility, $\Delta\chi$. When the molecular $\Delta\chi$ is positive the helix axis tends to align perpendicular to the magnetic field, B_0 . In this situation the director is distributed in a plane that contains B_0 . Very broad NMR spectra are then expected as there is not a homogeneous orientation of the director toward the magnetic field. However, if the field is larger than some critical field,⁷ particular to each liquid crystal system, the field unwinds the supramolecular cholesteric helix, thus giving rise to a chiral nematic phase where high resolution NMR may be achieved. The situation is more interesting when the molecular $\Delta\chi$ is negative. Then the supramolecular helix axis orientates parallel to B_0 and consequently the director is distributed in a plane perpendicular to the magnetic field. The director orientation is then expected to be homogeneous and at 90° to B_0 . Unfortunately, it has been shown^{8,9} that in this situation the director generally does not orientate homogeneously enough to provide high-resolution spectra. This has been attributed to existing textural defects due to visco-elastic forces that the magnetic field cannot overcome. This is an unfavorable effect that prevented development of NMR in such chiral-oriented solvents, even if they were expected to act differently on enantiomers.

In 1968, Snyder et al. performed a clever experiment.¹⁰ Realizing that the supramolecular helicity of the cholesteric phase was the origin of the low quality of the orientation, they made up a chiral nematic solvent from a compensated mixture of two different cholesteric compounds of opposite helicity. By using racemic 3,3,3-trichloropropylene oxide as a guest molecule, they announced that they obtained separate spectra for each enantiomer (Figure 1). Unfortunately, the linewidths were still rather large and the solvent used, a mixture of cholesterol derivatives, prevented any development of this technique.

In 1975, Tracey and Dieh¹¹ reported a small ¹H NMR separation observed for *D*-*L* alanine when dissolved in a lyotropic liquid crystal made of sodium *n*-decylsulfate doped with chiral sodium decyl-2-sulfate (Figure 2). This experiment, which may be seen as the first chiral discrimination using a cholesteric liquid crystal as solvent, has been reproduced several times by Tracey and Radley using lyotropic liquid crystals made of chiral polar head amphiphiles.^{12–15} In these

Figure 1 60 MHz proton spectrum of racemic 3,3,3-trichloropropylene oxide in a liquid crystal solvent. The lower trace solvent was a classical nematic. The upper trace solvent was made of a mixture of 0.53 g of cholesteryl chloride and 0.28 g of cholesteryl myristate. Note the apparent doubling of the external lines when using this compensated nematic mixture of cholesterics. (Reproduced by permission of the American Chemical Society from Sackmann et al.¹⁰)

Figure 2 (a) The methyl proton resonance at 100 MHz from *D*-alanine in the chiral lyotropic phase described in the text. (b) The methyl resonance of a non-racemic mixture of *D*- and *L*-alanine. Clearly there are two superimposed spectra corresponding to the enantiomers. (Reproduced by permission of North-Holland Publishing Company, Amsterdam, from Tracey et al.¹¹)

experiments, the spectroscopic separation between the alanine enantiomers were correlated to the cholesteric pitch to inquire about the origin of the micelle to micelle twist. No practical applications to measuring enantiomeric excess developed, mainly because these liquid crystals are difficult to orient homogeneously in the magnetic field and also because proton NMR was used, and consequently only the study of very small molecules was possible.

Independently, in the 1960s, considerable attention was devoted to the cholesteric liquid crystal properties of organic solutions of some synthetic homo-polypeptides such as poly- γ -benzyl *L*-glutamate (PBLG).^{16–19} In 1967 three sets of workers, Samulski and Tobolski,²⁰ Sobajima²¹ and Panar and Philips,²² independently found that the ¹H NMR spectrum

of CH₂Cl₂ is split into a doublet in the liquid crystalline phase PBLG/CH₂Cl₂. This result indicates clearly that, in a strong magnetic field, the supramolecular pitch is unwound due to the bulk anisotropy of the diamagnetic susceptibility, thus producing a cholesteric to chiral-nematic transition. This medium thus furnishes a very interesting oriented solvent for high resolution NMR.²²

Most of the work done between 1965 and 1990 was essentially dedicated to the study of the rather unusual liquid crystal properties of these polymeric solutions.²³ Nevertheless, in 1981, Czarniecka and Samulski²⁴ noticed that the enantiotopic deuterons in benzyl alcohol-d₇ give each a quadrupolar doublet when dissolved in PBLG liquid crystal solution. This means that in such a chiral anisotropic medium enantiotopic nuclei are not equivalent, as they are in non-chiral liquid crystalline solvents. We will see later that this finding has important consequences regarding isotopic chirality.

In 1989, our group presented a new chiral liquid crystal solvent made of a mixture of cholesteryl propionate (60%) and ZLI-2806 (40%), the latter being a commercially available nematic eutectic mixture of different cyano-bicyclohexyl derivatives.²⁵ This cholesteric $\Delta\chi < 0$ mixture has the unique property to orient homogeneously with the helicity axis parallel to the NMR magnetic field. In this situation, the director being entirely perpendicular to B₀, good high-resolution dipolar spectra were obtained for dissolved molecules. The next step was to study the high-resolution spectrum of a simple chiral molecule using the above solvent. The first ¹H spectrum obtained using racemic 3,3,3-trichloropropylene oxide is shown in Figure 3. Due to the size of the dipolar couplings an ABC pattern was expected for the three spin system and two superimposed ABC patterns are easily visible, one spectrum for each enantiomer.

An analysis of the sub-spectra attributed to each enantiomers has been realized, and lead to the following results:

- In each sub-spectra the chemical shifts and the scalar couplings are the same within experimental error.
- The only difference between the spectra originates from a difference in the inter proton dipolar couplings.

The importance of this last point is seen when looking at the parameters involved in the dipolar coupling:

$$D_{ij} = - \left(\frac{\mu_0}{4\pi} \right) \frac{\hbar \gamma_i \gamma_j}{4\pi^2 r_{ij}^3} \cdot \frac{1}{2} \langle 3 \cos^2 \theta_{ij}^z - 1 \rangle$$

It is clear that the observed difference in the dipolar couplings cannot come from the magnetogyric ratios γ_i and γ_j because the same nuclei are involved in the enantiomers. The difference also cannot come from the internuclear distance r_{ij} since symmetry through a plane keeps distances constant. So it must be concluded that the dipolar coupling difference between the enantiomers originate from a difference in the so-called order parameters, $S_{ij} = \langle 3 \cos^2 \theta - 1 \rangle / 2$, of the internuclear vector, θ being the angle between the ij direction and the magnetic field and the brackets meaning an ensemble average over the anisotropic molecular motion.

The fundamental conclusion is that two enantiomers are not ordered in the same way when dissolved in a cholesteric liquid crystal, $S_s \neq S_r$, and consequently all the order sensitive NMR parameters are in principle different: the dipolar coupling as

Figure 3 250 MHz proton spectrum of racemic 3,3,3-trichloropropylene oxide obtained in the cholesteric liquid crystal described in the text, together with the simulated ABC sub-spectra associated with each enantiomer

we have shown, but also the chemical shift anisotropy and the quadrupolar coupling for a spin larger than one half.

Unfortunately, no efficient applications can be made using spectra dominated by dipolar couplings except for very simple molecules. This is because of the tremendous complexity of second order dipolar spectra, which is due to the large values of the dipolar couplings compared to chemical shift differences. Actually, it is possible to overcome this problem using proton-decoupled deuterium NMR.²⁶ Now the spectra are dominated by the deuterium quadrupolar couplings. It is well known that quadrupolar interaction is purely anisotropic and a nucleus with $I = 1$ depends on the ordering through the following relationship:

$$\Delta\nu_Q = \frac{3e^2qQ}{2h} \cdot S_{CD}^Z$$

where $3e^2qQ/2h$ is the quadrupolar coupling constant for the deuterium and $S_{CD}^Z = \langle 3 \cos^2 \theta_{CD}^Z - 1 \rangle / 2$ is the order parameter of the C–D vector, with θ_{CD}^Z being the angle the C–D direction makes with B_0 . Here it is assumed that the electric field gradient is symmetric along the CD bond. Let us then assume a monodeuterated chiral molecule D–C*($R_1 R_2 R_3$). The proton decoupled deuterium NMR of such a compound in an isotropic solvent will result in a single line centred at the isotropic

chemical shift. Using a non-chiral liquid crystal as the solvent we will observe a doublet with spacing $\Delta\nu_Q$ due to the quadrupolar splitting. Now, in a chiral liquid crystal, whenever the enantiomers are not ordered the same, we should observe two quadrupolar doublets, one for each enantiomer, as depicted in Figure 4(c).

This is exactly what was observed as may be seen in the example shown in Figure 5. It is clear that integration allows an eventual enantiomeric excess to be measured very easily using this very simple 1D NMR experiment.

3 CHIRAL DISCRIMINATION USING POLYPEPTIDIC LYOTROPIC LIQUID CRYSTALS

Working for a while with the above thermotropic cholesteric mixture²⁷ lead to two conclusions. The first one is positive as essentially this technique works with almost everything contrary to conventional methods. It does not require a specific strong interaction between the chiral solute and solvent molecules. Here the discrimination between enantiomers arises from a difference in molecular orientational order, or in other words how the *R* and *S* molecules install themselves in the most “comfortable situation” among the chiral liquid crystal molecules. The second one is negative: the cholesteric mixture used so far is based on cholesterol esters, and it must appear evident that this steroidal compound is anything but a good solvent! Consequently we started to search for other chiral liquid crystals that could both exhibit this differential ordering effect of enantiomers and be good solvents and easier to use than thermotropic cholesterics. It was during a visit of Loewenstein as an invited professor in Orsay that we began to use polypeptidic lyotropic liquid crystals²⁸ and this has been very rewarding. The main advantages of these chiral lyotropic mesophases are listed below.

- The samples are easy to prepare: the polymer is dissolved in an organic solvent such as chloroform, methylene chloride, dimethyl formamide or many other helicogenic solvents. The resulting mixture is a good solvent for many organic compounds to be studied.
- The order parameters of molecules dissolved in such chiral liquid crystal are small, generally one to two orders of magnitude smaller than in thermotropics ($S \cong 10^{-3} - 10^{-4}$). This is useful because the sense that second order effects are limited compares to thermotropics.
- The chiral differentiation power of these media is absolutely fantastic. It works with almost everything, alcohols, amines, ethers, ketones, acids,²⁹ aminoacids,³⁰ organo-metallic complexes, alkynes, alkenes and even with alkanes.³¹

The three NMR anisotropic interactions may be used to differentiate enantiomers, the quadrupolar splitting for nuclei with $I > 1/2$, essentially deuterium, the chemical shift anisotropy or the dipolar spin-spin coupling. Examples for each case are described below.

Many homopolypeptides may be used. The most common are poly- γ -benzyl L-glutamate (PBLG) and poly- ϵ -carbobenzoxy L-lysine (PCBLL). Furthermore, it is often interesting to make spectra using a racemic mixture of PBLG and PBDG, its enantiomer synthesized from D-glutamic acid. In

Figure 4 Schematic representation of the effect of a difference in the ordering of enantiomers on the NMR spectra when observing the following interactions (a) chemical shift anisotropy (b) dipolar coupling (c) quadrupolar splitting. (Reproduced by permission of the Royal Society of Chemistry from Sarfati et al.⁴¹)

such a solvent all the effects coming from the chirality of the solvent disappear.

4 CHIRAL DIFFERENTIATION USING QUADRUPOLEAR SPLITTING

The principles have been described above. If two deuterated enantiomers are not ordered the same in the polypeptide lyotropic liquid crystal then a quadrupolar doublet will be observed, one for each enantiomer.²⁹ In Figure 6 is an example on an allenic compound.

Clearly, the quadrupolar splitting is without contest the most sensitive to order differences as, in a diamagnetic molecules, it is the strongest NMR interaction. The main disadvantage is of course that it is necessary to deuterate selectively the molecules because natural abundance deuterium content, 0.015%, is too small to be of routine use at the moment (see Section 9 for the perspectives).

Beside deuterium other quadrupolar nuclei may be used, in the extent where the quadrupolar relaxation is long enough to provide high-resolution spectra. Some interesting applications have been discussed by Hosseini et al. involving ¹³³Cs, ¹¹B or ¹⁴N NMR on different ions inserted in chiral cages.³²

5 CHIRAL DIFFERENTIATION USING CHEMICAL SHIFT ANISOTROPY

It is possible to obtain a chiral discrimination via a difference in the anisotropy of the chemical shift, $\Delta\sigma$, which is also sensitive to order parameters through:

$$\Delta\sigma = \frac{2}{3} \sum \sigma_{\alpha\beta} S_{\alpha\beta}$$

where $S_{\alpha\beta}$ are the elements of the order matrix and $\sigma_{\alpha\beta}$ are the elements of the electronic screening tensor expressed in the same frame. To illustrate the expected effect consider a ¹³C nucleus in a chiral molecule. Following Figure 4(a), the proton-decoupled spectrum obtainable in classical isotropic NMR is a single line centred on the isotropic shift, ν_i^{iso} . Using a non chiral nematic solvent the resonance frequency will be different as the chemical shift anisotropy is not averaged to zero anymore, $\nu_i^{\text{aniso}} = \nu_i^{\text{iso}} + \Delta\nu$, where $\Delta\nu = \gamma B_0 \Delta\sigma / 2\pi$. Here again, $\Delta\nu$ depends on the order parameters and consequently if two enantiomers are not ordered the same we can have $\Delta\nu_R$ different to $\Delta\nu_S$. This will split the signal in two lines, one for each enantiomer. This is exactly what is observed in Figure 7 for most of the aromatic carbons of an enriched mixture of 1,1'-bi-2-naphthols.

Nevertheless, to be efficient this method needs nuclei with a large chemical shift anisotropy. It has been rather successful

Figure 5 250 MHz proton decoupled deuterium spectrum of a chiral alcohol dissolved in the cholesteric liquid crystal described in the text. Note that we see two quadrupolar doublets, one for each enantiomer. (Reproduced by permission of Taylor and Francis Ltd from Courtieu et al.²⁶)

Figure 6 61.4 MHz proton-decoupled deuterium spectrum of a racemic mixture of an allenic alcohol dissolved in the PBLG-CH₂Cl₂ chiral liquid crystal system. Note again a quadrupolar splitting for each enantiomer

using sp and sp^2 ^{13}C , ^{19}F in $-\text{N}-\text{CO}-\text{CF}_3$ group,³⁵ ^{77}Se NMR. But the chemical shift anisotropy is generally too small to give measurable effects using NMR on the following nuclei ^1H , ^2H , sp^3 hybridized ^{13}C , ^{19}F in fluorocarbons, ^{31}P in phosphine

Figure 7 100.1 MHz proton-decoupled carbon-13 spectrum of a non-racemic mixture of the enantiomers of binaphthol dissolved in the PBLG-DMF- d_7 chiral liquid crystal. Note the chiral separation due to the chemical shift anisotropy on many of the ^{13}C transitions. (Reproduced by permission of the American Chemical Society from Meddour et al.³⁴)

oxides. So using chemical shift anisotropy is far from general and less efficient than the deuterium quadrupolar splitting. However, whenever it works no chemistry is involved to discriminate enantiomers and the use of higher fields will make it more efficient.

6 CHIRAL DIFFERENTIATION USING DIPOLAR COUPLING

Dipolar spin-spin couplings are also sensitive to ordering and may be used to differentiate enantiomers.³⁴ As already described, inter proton dipolar coupling will generally not be measurable using ^1H NMR. Indeed, the large number of couplings, even if they are small with this liquid crystal solvent, usually makes proton NMR lines not resolved. But the rather large dipolar ^{13}C – ^1H coupling may often be used. To see the effect consider an isolated ^{13}C – ^1H in a chiral molecule. Using isotropic proton coupled ^{13}C NMR we will observe a doublet due to the isotropic part of the scalar coupling, J_{CH} ,

as shown in Figure 4(b). In a non-chiral nematic solvent the same experiment will also furnish a doublet but with a different line spacing. This is due to the ^{13}C – ^1H dipolar coupling that adds to the scalar: $\Delta\nu = J_{\text{CH}} + 2D_{\text{CH}}$. As D_{CH} is sensitive to order, using a chiral liquid crystal will yield two doublets, one for each enantiomer, when the dipolar couplings are different enough for the R and S enantiomers. Such an experiment is shown in Figure 8 for different enantiomeric mixtures of ($\pm$)- β -(trichloromethyl)- β -propiolactone.

The method is rather general, though less efficient than deuterium NMR. The main limitation here arises when numerous long distance dipolar and scalar couplings make the ^{13}C linewidth large and unresolved. But it works very nicely as soon as there is an isolated group like $-\text{COO}-\text{CH}_3$ for instance. Again the advantage here is that no chemistry is involved. It may be noted also that the method works rather well using ^{19}F – ^{19}F dipolar coupling in poly-fluorinated compounds.³⁵

7 VISUALIZING ISOTOPIC CHIRALITY

One of the most remarkable properties of these polypeptide liquid crystals is their ability to distinguish perfectly well enantiomers of chiral molecules by virtue of isotopic substitution.⁴² An example is shown in Figure 9 of the monodeutero-propionic acid.

In this case the differentiation does not come from a difference in the ordering of the enantiomers. Intuitively, the small difference in geometry between a proton and a deuterium could not produce a differential ordering effect as large as that in Figure 9. Here the discrimination comes from the symmetry properties of the orientational distribution function, which may be lower than the molecular point group symmetry.⁴⁴ For instance, for a molecule having a plane of symmetry, C_s , the orientational distribution function in a chiral liquid crystal has no symmetry, C_1 , due to the orientational

Figure 8 101.1 MHz proton-coupled carbon-13 spectra of the methine group of ($\pm$)- β -(trichloromethyl)- β -propiolactone in PBLG- CD_2Cl_2 chiral liquid crystal solvent. (a) Racemic mixture. (b) R (+) enriched mixture, 40% ee . (c) pure R (+) enantiomer. (Reproduced by permission of the Royal Chemical Society from Lesot et al.³³)

Figure 9 38.4 MHz proton-decoupled deuterium spectrum of R -enriched mixture of $\text{CH}_3\text{-CHD-COOH}$ enantiomers (ee 72%) dissolved in PBLG- CD_2Cl_2 chiral liquid crystal. (Reproduced by permission of the American Chemical Society from Meddour et al.⁴²)

Figure 10 (a) 61.4 MHz natural abundance Q-COSY 2D deuterium spectrum with proton decoupling of a racemic mixture of 4-penten-2-ol. Note that chemical shifts appear along the main diagonal and that quadrupolar doublets lie perpendicular to the diagonal. (b) Same spectrum after a 45° tilt of the 2D matrix. Note that a quadrupolar decoupled spectrum appears in dimension one and that a column extracted at a given chemical shift furnishes a very simple spectrum: a quadrupolar doublet for each enantiomer. Two such columns are shown on the right of the figure. (Reproduced by permission of The Owner Societies from Merlet et al.⁴³)

chiral field. This means that enantiotopic deuterons in such a C_S molecule are not equivalent as is the case in non-chiral solvents. Consequently one observes a quadrupolar doublet for the pro-*S* and an other one for the pro-*R* deuterons. The chiral discrimination of isotopic enantiomers appears then as a simple consequence of the inequivalence of enantiotopic nuclei.

8 USING ACHIRAL DERIVATIZING AGENTS

When deuteration is not possible and when neither the CSA nor the dipolar coupling give good results there may be the opportunity to use derivatizing agents. Contrary to the classical method in isotropic solvents one does not

need chiral agents when using a chiral solvent, but we do need deuterium nuclei in the agent.^{36–40} These achiral, but deuterated, derivatizing agents have the advantage when compared to their chiral equivalent because they react at the same rate with enantiomers and consequently no care has to be taken about the completeness of the reaction.

9 USING NATURAL ABUNDANCE DEUTERIUM

Clearly the deuterium quadrupolar splitting is the most useful way of detecting differences in orientational order. But it generally needs the synthesis of labelled compounds, which may be difficult. Is it possible to work at natural abundance level? Two problems have to be resolved to do so. First, the spectra are going to be quite crowded because we are expecting two quadrupolar doublets for all the possible isotopomers. Second, we will have a severe sensitivity problem as deuterium is only 0.015% abundant. This very low natural abundance results in one of the less sensitive nuclei in the periodic table, 1.45×10^{-6} , relative to proton.

The spectrum-crowding problem has been solved using a specific 2D experiment.⁴³ The sequence $90^\circ - t_1 - 180^\circ - t_2$ produces a total single quantum coherence transfer between the quadrupolar doublets, resulting in a very simple 2D pattern where the chemical shifts appear along the diagonal and the quadrupolar splitting perpendicular to the diagonal. This technique, called Q-COSY, allows a very straightforward assignment of auto-correlated quadrupolar doublets. An example is shown in Figure 10(a) where two quadrupolar doublets may be observed for each isotopomer of ($\pm$)-4-penten-2-ol. In Figure 10(b) the same spectrum is shown following a simple 45° tilt of the original spectrum resulting in a quadrupolar decoupled deuterium spectrum in dimension one. Extracting out a column of the 2D matrix gives a simple 1D spectrum with a doublet for each enantiomer that allows an eventual enantiomeric excess (*ee*) to be measured.

The 2D proton-decoupled deuterium spectra in Figure 10 were obtained at natural abundance levels using a solution containing 100 mg of the molecule and 17 hours acquisition time on a Bruker 400 MHz instrument equipped with a 5 mm o.d. BBI probe. Clearly the sensitivity has to be increased to get a precise *ee* measurement. But we think that higher magnetic fields joined with the use of a specific deuterium cryoprobe could solve the sensitivity problem. Then this technique would become some kind of a panacea for enantiomeric measurements.

10 SUMMARY

When dissolved in polypeptidic lyotropic liquid crystals enantiomers are not ordered the same and consequently all the anisotropic NMR observables are different. This technique, which allows measurements of enantiomeric excesses, is still in its infancy. Many other stereochemical problems need to be addressed. Among them are the differentiation of enantiotopic nuclei⁴² and the visualization of diastereoisomers with remote stereogenic centres.⁴⁵

One challenging question remains open: are we going to be able to predict the absolute configurations non-ambiguously?

This is an old dream of the NMR spectroscopist, but there is still a lot to do to succeed on this point.

1 INTRODUCTION

The unique properties of diamond, such as its high thermal conductivity, mechanical characteristics, optical transparency, and semiconductor characteristics, make it an attractive material for many applications.¹ Synthetic diamond powders and single crystals were first made in high-pressure/high-temperature (HPHT) processes in the 1950s. More recently, diamond films have been grown at technologically significant rates using a variety of subatmospheric chemical vapor deposition (CVD) processes. The primary distinction between these CVD techniques is the method by which energy is introduced in order to dissociate and excite the gas phase reactants.² Activation of the gas phase diamond precursors has been achieved by direct current (DC) plasmas, microwave (MW) plasmas, hot filaments, and combustion flames. Although significant variations in growth rates exist between these methods, all seem capable of producing highly faceted polycrystalline films with little evidence of nondiamond carbon and with low hydrogen concentrations (<0.5 at.%). Thus, diamond films are distinctly different from diamond-like carbon (DLC) films, which are amorphous, can have a significant fraction of sp²-bonded carbon, and can have >30 at.% hydrogen.³

The deposition of diamond at low pressures, where it is metastable, appears to involve a kinetic competition between the growth and etching of various forms of carbon ranging from diamond (tetrahedral sp³ bonded), through amorphous sp³ and sp² configurations, to graphitic carbon (sp²). The range of successful reactant compositions is surprisingly similar for the various types of CVD processes.³ Diamond films are most commonly deposited from a dilute mixture of hydrocarbons (0.5–2.0%), such as methane or acetylene, in hydrogen. However, studies of carbon sources containing oxygen (e.g. acetone, ethanol, and carbon monoxide) and halogens (fluorine and chlorine) have also shown promising results. The energy introduced into the gas phase produces molecular fragments and excited species which react on the surface of the substrate which is generally maintained at 800–1000 °C.

The hydrogen which is often predominant in the gas phase has been proposed both to stabilize the growing diamond surface and to etch graphitic carbon.^{1–3} The electrical

resistivity of diamond has been proposed to depend on hydrogen incorporation.⁴ Also, increased hydrogen contents correlate with decreased transparency in the 8–10 μm wavelength region, degrading the performance of diamond as an infrared window.^{5,6} Thus, the location and distribution of hydrogen can provide insight into diamond deposition chemistry and structure–property relationships in these films.

The commercial exploitation of CVD diamond requires consistent high-quality production, and defect-free films and coatings. While many techniques have been used to evaluate diamond film quality, most provide only qualitative information on which to evaluate differences in deposition conditions. Hydrogen is particularly difficult to measure in solid thin films.⁷ The primary advantage of NMR measurements is their quantitative nature. In addition, the low-energy radiofrequency irradiation used in NMR is unlikely to result in chemical alteration of the diamond samples, unlike some higher-energy spectroscopic techniques. To date, diamond has been studied by ¹H,^{5–10} ¹³C,^{11–22} and ¹⁹F²³ NMR, often providing information which is unattainable by other techniques.

For static NMR measurements, one or more sections of a free-standing diamond film, generally >10 μm thick, may be inserted directly into the NMR sample coil.⁵ By not using a conventional NMR tube or rotor, a potential source of background signal is eliminated.⁷ This is a particularly important consideration when studying thin films, since sample sizes are generally limited and the concentration of NMR active nuclei is often low. In addition, the macroscopic integrity of the film is maintained. Similarly, laser-cut disks of free-standing diamond can be stacked into MAS rotors if examination of intact films is desired.²² Alternatively, powder, formed by crushing a film or removing a very thin film from its substrate, can be packed into an NMR tube or rotor.

In some instances, NMR spectra of films can also be acquired without removing their growth substrates.¹⁷ For such experiments, the substrate must be nonmagnetic, have a low conductivity, have a similar magnetic susceptibility to the diamond film, and must contribute little background signal for the nuclei to be observed. These conditions can be met by using high-resistivity silicon wafers manufactured by the float zone process. The use of thin wafers (≤75 mm in thickness) maximizes the number of film sections which can be inserted into the NMR coil.

2 CARBON-13

The isotropic chemical shift can resolve sp²- from sp³-bonded carbon. Bulk diamond is characterized by a single resonance at 36 ± 2 ppm¹¹ relative to tetramethylsilane (Figure 1).¹³ The sp² carbon peak generally appears between 120 and 200 ppm, with the lower values observed for amorphous carbon films,⁴ while soot gives a peak centered at 189 ppm.¹⁸ The ratio of sp²/sp³ bonded carbon is quantitatively determined from the ratio of the integrated area under the peaks corresponding to these respective environments and has been experimentally demonstrated for diamond powder and soot mixture of known weight fraction.¹⁸

The linewidth of the sp³ peak of natural diamond in the static ¹³C spectra is dominated by homonuclear dipole

Figure 1 Static direct polarization (DP) ^{13}C NMR at 67.9 MHz of 3 carats of gemstone natural diamonds. The $\Delta\nu_{1/2}$ of 250 Hz includes 50 Hz added Lorentzian broadening. (Adapted from Henrichs et al.)¹³

broadening. The second moment of this interaction can be calculated via the Van Vleck equation:^{12,25}

$$M_2 = \frac{3}{4} \gamma^4 \hbar^2 I(I+1) f \sum_k \frac{(1 - 3 \cos^2 \theta_{jk})^2}{r_{jk}^6} \quad (1)$$

where r_{jk} is the distance between two sites, and f is the fraction of these sites randomly occupied by the NMR-active nuclei of interest. The dependence on θ_{jk} , the angle the intersite vector makes with the external magnetic field, causes M_2 for a powdered sample to differ from that of a single crystal having an identical chemical structure. When active nuclear spins are dilute ($f < 0.01$), a truncated Lorentzian lineshape results, with a full width given by

$$\Delta\nu_{1/2} = \frac{\pi}{\sqrt{3}} \left(\frac{M_2^2}{M_4} \right)^{1/2} (M_2)^{1/2} \quad (2)$$

Note that the point chosen for truncation influences the ratio M_2^2/M_4 . For higher spin densities, a Gaussian lineshape is observed, with a linewidth of

$$\Delta\nu_{1/2} = 2.35(M_2)^{1/2} \quad (3)$$

These linewidths are independent of the applied magnetic field; hence, chemical shift resolution can be improved at higher fields.

Using equation (1) for a diamond lattice with a natural abundance of ^{13}C ($f = 0.011$) yields $M_2 = 0.037 \text{ kHz}^2$ for a single crystal oriented with its (014) axis parallel to the external magnetic field, which compares favorably with the measured value of $M_2 = 0.041 \text{ kHz}^2$, confirming that homonuclear dipolar interactions are the dominant source of broadening in this environment.¹² The corresponding observed lineshape is a truncated Lorentzian with $\Delta\nu_{1/2} = 200 \text{ Hz}$,¹² similar to that shown in Figure 1.¹³

In materials with high hydrogen concentrations, like polymers and DLC films,²⁴ CP can be used to enhance the ^{13}C spectrum. However, variations in CP dynamics can cause the quantitative character of the NMR experiment to be lost. The low hydrogen concentrations found in polycrystalline diamond films make CP difficult, although achievable.¹⁴ In the vicinity of hydrogen, where CP is most efficient, only sp^3 -bonded carbon nuclei were detected. Also, because ^1H - ^{13}C heteronuclear dipole couplings are generally negligible in diamond films, proton decoupling is often not required. Direct polarization

(DP) ^{13}C NMR, while requiring larger samples, is a means of obtaining quantitative sp^2/sp^3 ratios. Typically, $>5 \times 10^{18}$ ^{13}C nuclei are required,¹⁸ corresponding to $\sim 10 \text{ mg}$ of a natural abundance diamond, which is equivalent to a $10 \mu\text{m}$ thick film over an area of 2.8 cm^2 .

In samples which are free of paramagnetic defects, DP NMR experiments are quantitative in that each ^{13}C nucleus gives rise to the same integrated signal intensity, regardless of its bonding environment. In samples containing paramagnetic impurities, a small fraction of nuclei in close proximity to such defects will remain undetected as a result of extreme line broadening due to interaction with the unpaired electron of the paramagnetic impurity.^{12,13} However, only a small fraction of nuclei should be affected by the paramagnetic densities (10^{17} – 10^{18} g^{-1}) in diamond films.^{20,21} This assumption can be verified by comparing the experimental signal intensity to the expected intensity based on mass and ^{13}C enrichment in the sample and response of the spectrometer to standards of known ^{13}C content. Fortunately, these experiments show that the effects of broadening by paramagnetic centers are often below the NMR detection limit.¹⁸ For quantitative measurements, it is also important to insure that a sufficient delay ($\geq 5T_1$) is used between signal acquisitions.

Isotopic enrichment can be used to decrease sample size requirements.^{17–19,21} The spin–lattice relaxation rate will also increase as a result of enhanced spin diffusion in the ^{13}C -enriched samples. Both factors lead to increased sensitivity and/or decreased acquisition times. The concentration of ^{13}C in the solid film can be determined via the second moment of the homonuclear dipole couplings [see equation (1)]. The degree of enrichment determined in this manner is in excellent agreement with measurements of the isotopic shift of the diamond one-phonon absorption in the Raman spectra.¹⁹ However, enrichments $>25\%$ will limit spectral resolution of sp^2 versus sp^3 carbon due to homonuclear dipolar line broadening [see equation (1)]. Resolution may be restored by MAS at speeds greater than the ^{13}C – ^{13}C homonuclear dipole broadening in hertz, i.e. spinning frequencies of more than 4 kHz.

Selective isotopic labeling can be used to gain insight into the chemistry of diamond formation when more than one chemically distinct carbon is present in the gas phase reactant mixture.^{17–19} For instance, films have been grown using acetone, selectively ^{13}C labeled at either the methyl or carbonyl site, as the reactive carbon source. Measuring the resulting ^{13}C concentration in a pair of otherwise identical films determines the relative efficiency at which the methyl and carbonyl sites from the selectively labeled acetone are incorporated into diamond. When such experiments are carried out in a hot filament reactor, both labels are incorporated equally when a tantalum filament is used.^{17,18} In contrast, diamond deposits preferentially from the methyl site when a rhenium filament is employed.¹⁹ However, some growth from the carbonyl site is still observed when rhenium is used. Such experiments demonstrate the importance of heterogeneous chemistry at the filament in this type of CVD reactor.

In polycrystalline CVD films, the diamond peak is nearly symmetric, revealing little CSA, as expected for a tetrahedrally symmetric bonding environment. For static spectra, the $\Delta\nu_{1/2}$ ranges from 310 to 500 Hz in unenriched films,^{18,21} indicating broadening in addition to homonuclear dipole interactions. MAS at sufficient speeds can average broadening due

Figure 2 Static DP ^{13}C NMR at 75 MHz of two CVD diamond films, enriched to 22% ^{13}C . (a) The highly faceted film shows only the 36 ppm resonance characteristic of sp^3 bonding environments. (b) A broader sp^3 peak and a second peak at ~ 120 ppm due to sp^2 carbon are seen in the second film, which also has much poorer morphology. (Adapted from McNamara et al.)¹⁸

to dipolar interactions, CSA, and variations in magnetic susceptibility. Thus, any remaining broadening can be attributed to a wider distribution of bond angles and lengths in the film. A highly faceted hot filament film on its substrate, with 22% ^{13}C enrichment, produces a symmetric Gaussian lineshape with $\Delta\nu_{1/2} \sim 3$ kHz [Figure 2(a)],¹⁷ in reasonable agreement with equations (1) and (3). Upon crushing this sample and performing MAS, the $\Delta\nu_{1/2}$ was reduced to 150 Hz. Variations in MAS $\Delta\nu_{1/2}$ from 6 to 55 Hz in natural abundance samples have been linearly correlated to increases in Raman one-phonon linewidth, which is also associated with increasing disorder of the diamond phase.²¹

Asymmetry in the sp^2 peak is expected as a result of CSA and/or bond angle disorder. Unfortunately, sp^2 -bonded carbon in visibly faceted films produced via hot filament, DC arc jet, or MW plasma CVD is generally below the ^{13}C NMR detection limit.¹⁸ An sp^2 resonance has been observed in a film of poor morphology and no detectable diamond one-phonon Raman absorption.¹⁷ This film was prepared under identical conditions to the highly faceted hot filament film discussed above [Figure 2(a)], with the sole exception that the C/H ratio in gas feed was increased, resulting in poorer film quality. The static NMR spectra of this 22% enriched film, intact on its substrate, resolves both broad sp^2 and sp^3 peaks at ~ 120 and ~ 38 ppm, respectively [Figure 2(b)]. The ratio of the areas of these two peaks gives a quantitative sp^2/sp^3 ratio of 0.11 ± 0.2 , indicating that $\sim 10\%$ of the carbon in this film is bonded in an sp^2 configuration. The MAS linewidth of the sp^3 peak narrows to only $\Delta\nu_{1/2} = 690$ Hz, indicating some disorder in the

sp^3 environment, while the lineshape of the sp^2 peak remains relatively unaltered, indicating a high degree of disorder in this phase.

Quantitative sp^2/sp^3 ratios measured by solid state ^{13}C NMR have been compared with qualitative results of Raman spectroscopy,¹⁸ one of the most widely used techniques for characterizing diamond thin films. Raman is sensitive to both the sp^2 and sp^3 bonding environments but is difficult to quantify since the scattering efficiency of sp^2 -bonded carbon differs from sp^3 -bonded material, and each may vary from film to film. In addition, the sp^2 - and sp^3 -bonded carbons may have different absorptivities, which can lead to nonuniform sampling as a function of depth in the film.

As expected, Raman spectroscopy is extremely sensitive to sp^2 -bonded carbon, identifying small amounts below the detection limit of the NMR spectrometer. Comparison of the two techniques, however, indicates that Raman spectroscopy may be so sensitive to sp^2 -bonded carbon that sp^3 -bonded carbon in films containing as much as 90% sp^3 -bonded material may remain undetected. This is undesirable when new deposition conditions are being explored, since conditions which yield a majority of sp^3 -bonded sites can be overlooked by the Raman analysis.

These two techniques also differ in that NMR spectroscopy is sensitive to short-range order, while Raman spectroscopy probes order over a longer range. NMR provides only information averaged over the entire sample volume and requires relatively large samples and long acquisition times. Raman spectroscopy has the advantage of giving fast, spatially resolved information. A combination of the two techniques is desirable for obtaining reliable information for all types of diamond.

Another method for enhancing the sensitivity of NMR for characterizing diamond films is DNP.^{20,21} The work on diamond films builds upon earlier DNP investigations of natural and HPHT diamond.^{15,16} Polarization from paramagnetic defects is transferred to the nuclear spin reservoir by simultaneous irradiation at the electron spin and ^{13}C Larmor frequencies. The ^{13}C nuclei close to paramagnetic sites polarize most quickly. Thus, the local composition can be investigated as a function of distance from the paramagnetic sites using variable contact time experiments. Often DNP is combined with MAS in order to suppress spin diffusion.¹⁶ When DNP is combined with CP from ^1H nuclei, hydrogenated regions can be selectively probed.^{20,21}

The 1.4 T ^{13}C DNP MAS spectra of CVD diamond have been published for an 83 mg natural abundance sample (Figure 3) and for two $\sim 14\%$ enriched samples of 20 and 29 mg, respectively. Although acquisition time is reduced by using DNP, this advantage is somewhat offset by the use of high magnetic fields by the more commonly available conventional NMR spectrometers.²⁰ The ^{13}C DP MAS spectra of the enriched samples was also acquired on a conventional NMR spectrometer, using a 14 T magnet.²¹ In addition, the static DP spectra of the same three samples had previously been reported using a 7 T NMR spectrometer.¹⁸

The main feature of the three DNP MAS spectra is a characteristic line at 36 ppm (Figure 3), which is also observed for bulk diamond. In some cases, a small, broad shoulder on this peak at ~ 45 ppm has been identified as hydrogenated sp^3 -bonded carbon through its response to both ^1H - ^{13}C variable CP contact times and dipolar dephasing experiments.²¹ This

Figure 3 Static DP-DNP ^{13}C NMR at 15 MHz of natural isotopic abundance CVD diamond film, showing only the characteristic peak for diamond. (Adapted from Lock and Maciel²⁰)

position falls in the calculated chemical shift range of 25–54 ppm for saturated hydrocarbons with an underlying diamond skeleton. These calculations start with adamantane and progress through fully hydrogen-terminated diamond surfaces, and are compared to experimental measurements where possible.²¹ A sharp peak centered at 28 ppm, observed only in DP MAS experiments may indicate freely rotating methyl groups. Only when intermediate ^1H – ^{13}C CP contact times were employed with the DNP MAS experiments was a broad, weak resonance observed at ~ 140 ppm in one of the enriched films. This peak was not observed using DNP MAS in the absence of CP, suggesting this sp^2 -bonded carbon is localized near hydrogenated sites. Unfortunately, the sp^2/sp^3 ratio could not be quantified because the polarization dynamics from both the paramagnetic defects and the proton reservoir are not well known in these samples.

3 PROTON NMR

Figure 4 shows representative ^1H NMR spectra, taken at a Larmor frequency of 270 MHz.^{5–10} Approximately 1500 signal transients were acquired at a repetition rate of 5 s, in accordance with typical proton T_1 s of less than 1 s in these samples, which contained $>10^{17}$ total proton spins. By not using an NMR sample tube and purging the NMR probe with dry nitrogen, the need for background subtraction was eliminated. Integrating such spectra yields concentrations ranging from <0.017 to ~ 0.5 at.% hydrogen, depending upon the exact film growth conditions used. The concentrations of hydrogen determined by NMR were used to quantify the CH_x stretching absorption in the infrared spectra of the same films. The infrared spectra reveal that the hydrogen is bonded covalently to the diamond lattice primarily as CH, CH_2 , and CH_3 groups,^{5,6} with some $-\text{OCH}_3$ and $-\text{NCH}_3$ moieties also possible.¹⁰

The ^1H spectra in Figure 4 are well represented by two components, a narrow Lorentzian and a broad Gaussian,⁵ as shown

Figure 4 Static ^1H NMR spectra at 270 MHz of a free-standing diamond film (solid lines). Two components are resolved at 300 K (middle), but the sharp Lorentzian is broadened when the temperature is decreased to 100 K (top). A 300 K 'hole-burning' experiment (bottom, dashed line) shows uniform attenuation of both components after selective irradiation of the small band, $\Delta\nu_{\text{sat}}$, indicating dipolar communication among the two resolved proton environments

by the solid line representing a least squares fit to the data, indicating at least two different bonding configurations for hydrogen in polycrystalline diamond. Similar two-component proton lineshapes, with different narrow to broad ratios, have been observed from films deposited by a variety of CVD processes.^{9,10} However, in CVD diamond with relatively high hydrogen concentrations, often only the broad feature can be resolved.²¹

A 'hole-burning' NMR experiment shows that these two resolved hydrogen environments are in close proximity.⁵ When a 1 kHz-wide region, 20 kHz from the center of the lineshape, was selectively saturated, uniform attenuation of both components is observed after a 2 ms delay (Figure 4). This indicates that rapid dipolar communication occurs between protons in the two environments, requiring internuclear distances of less than 50 nm. Figure 4 also shows that at 100 K the Lorentzian component is broadened, while the Gaussian component is not significantly affected.⁵ Thus, at room temperature, the narrow Lorentzian lineshape results from motional averaging, while the broad Gaussian line indicates rigidly held hydrogen. The CRAMPS ^1H spectra show an unresolved peak centered at ~ 2 ppm.²⁰

The homonuclear broadening resulting from static distributions of hydrogen bonded in a rigid polycrystalline lattice can be calculated by the van Vleck equation [see equation (1)]. For polycrystalline diamond samples, if all the hydrogen in the Gaussian component were randomly distributed as CH, the resulting $\Delta\nu_{\frac{1}{2}}$ range would be more than

two orders of magnitude smaller than typically observed values of ~ 60 kHz. Randomly dispersed CH_2 groups also provide too little homonuclear broadening. These discrepancies indicate locally high hydrogen concentrations, requiring significant segregation of hydrogen in polycrystalline diamond.^{5,6} However, this analysis cannot distinguish between isolated small clusters and larger groupings of spins.

Possible locations for segregation are hydrogen-decorated defects and voids within the crystal, a heavily hydrogenated phase stable at the deposition temperature or at the grain boundaries in polycrystalline diamond.⁵ If hydrogen was uniformly distributed on a surface, a density of $3 \times 10^{15} \text{ H cm}^{-2}$ would be required to give the observed $\Delta\nu_{\frac{1}{2}} = 60$ kHz. This compares favorably with areal densities of 3.1×10^{15} , 2.2×10^{15} , and $1.8 \times 10^{15} \text{ H cm}^{-2}$ for fully hydrogen passivated, unreconstructed $\langle 100 \rangle$, $\langle 110 \rangle$, and $\langle 111 \rangle$ diamond surfaces, respectively. In order to account for the NMR-observed bulk hydrogen incorporation of 0.01–0.22 at.%, monolayer hydrogen coverage of films composed of 0.5–150 μm cubes is required, dimensions which compare favorably to observed crystallite sizes in CVD films.⁶ The structure of hydrogenated surfaces present during growth may resemble those preserved at grain boundaries, which would allow these ^1H NMR measurements to act as a potential test of surface chemistry models of diamond growth.

The assumption of a surface distribution of hydrogen in polycrystalline diamond films is also supported by multiple quantum (MQ) NMR studies.⁸ Figure 5 shows the rate at which groups of protons are effectively correlated with increasing dimensionless MQ excitation time, $M_2^{1/2} \tau$, for

Figure 5 The number of effectively correlated protons (N) versus the dimensionless MQ excitation time, $M_2^{1/2} \tau$. The CaH_2 data ($\bullet$) fall on the universal curve for MQ growth of three-dimensional proton distributions. This growth is faster than for two-dimensional systems, represented by the hydrogenated diamond powder data ($\diamond$). The MQ growth of the three different CVD samples ($\square$, CVD-1; $\triangle$, CVD-2; $\circ$, CVD-3) is similar to that of the hydrogenated diamond powder at early excitation times. Nearly 20 protons are correlated in these films which have <0.5 at.% hydrogen, confirming the presence of large-scale hydrogen segregation. (Adapted from Levy and Gleason⁸)

two hot filament diamond films (CVD-1 and CVD-2) and one DC arc jet film (CVD-3). Initially, the data for the films are coincident with a known surface distribution of protons, hydrogenated diamond powder, and slower than that of known bulk hydrogen distributions, such as exist in CaH_2 . Up to 20 spins were correlated in the films despite the very low (<0.1 at.%) bulk concentrations, confirming the large-scale clustering of hydrogen, most likely in a two-dimensional distribution. The morphology of hydrogen incorporated into these films, as determined by MQ NMR, depends only weakly on the manufacturing process, suggesting that similar surface chemistry has occurred in both types of reactors.

4 FLUORINE-19 NMR

The lower substrate temperatures which have been achieved using fluorine-containing CVD reactants²⁶ opens the possibility of depositing diamond onto materials of low thermal stability, such as organic polymers. In addition, fluorination has been proposed to enhance the chemical inertness and lower the coefficient of friction of diamond surfaces.²⁷ Thus, knowledge of surface passivation of diamond by fluorine is desirable.

Solid state ^{19}F NMR has been used to characterize the surfaces of diamond powder after 100% CF_4 and 98% $\text{CF}_4/2\%$ O_2 radiofrequency plasma treatments.²³ The pure CF_4 plasma results in $7.1 \times 10^{14} \text{ F cm}^{-2}$, a coverage equivalent to approximately half of the available surface bond density. With the addition of 2% O_2 , the equivalent coverage is reduced by roughly an order of magnitude, to $7.4 \times 10^{13} \text{ F cm}^{-2}$. MQ NMR reveals that ^{19}F is not distributed uniformly on either surface.

High-speed MAS was used to average the effects of chemical shift anisotropy (Figure 6). On both surfaces, only CF_x ($x = 1-3$) functionalities were observed, with the predominant species being carbon monofluoride. Only 5–10% of the fluorine was bonded as CF_3 . The isotropic chemical shifts were resolved and assigned relative to CFCl_3 as follows: $\text{CF} = 148 \pm 1$ ppm; $\text{CF}_2 = 106 \pm 2$ and 123 ppm; $\text{CF}_3 = 78 \pm 1$ ppm. The peak at 123 ppm was only observed in the CF_4/O_2 plasma-treated sample, and is speculated to be the result of atomic fluorine etching of diamond.

5 SPIN-LATTICE RELAXATION

Paramagnetic defects facilitate spin-lattice relaxation in both natural and synthetic diamond.^{12,13} At a fixed degree of enrichment, an increase in the ^{13}C T_1 qualitatively indicates a lower relaxation center density, hence an increase in crystal quality. The T_1 s of commercial natural diamond powder are on the order of tens of seconds, while significantly longer time constants, on the order of a few hours, can be observed for large, gem-quality natural diamonds. An increase in T_1 has also been observed within a series of CVD diamond films as the morphology, observed by scanning electron microscopy, improved.¹⁷ However, detailed quantitative studies of T_1 behavior, analogous to those on single crystal diamond,¹² are often hindered by the higher complexity of defect distributions in the polycrystalline films.

Paramagnetic defects in diamond result from either unsatisfied bonding arrangements, so-called dangling bonds, present

Figure 6 Room-temperature, high-speed (15 kHz) MAS ^{19}F NMR spectra at 376.5 MHz of diamond powder surfaces, fluorinated by two different methods. (Adapted from Scruggs and Gleason²³)

either internally or at the surface of a crystal or from impurity incorporation. Nitrogen is a common impurity that gives rise to a variety of ESR-active centers.²⁸ Often these sites act as color centers, providing a visible manifestation of their presence. Boron incorporation imparts a blue color, and is sometimes intentionally used to produce p-type semiconducting diamond (type IIb).¹² However, most impurities are unintentionally introduced. For example, ferromagnetic impurities originating from the catalyst are common in HPHT synthetic diamond, and metallic impurities from the hot filament used are common in this variety of CVD film.

The ^{13}C spin-lattice relaxation of diamond can be described by²¹

$$M(t) = M_0[1 - \exp[-(t/T_1)^x]] \quad (4)$$

where x is constrained by the limits, $0.5 \leq x \leq 1.0$, and M_0 is the equilibrium magnetization. For the upper bound, $x = 1.0$, equation (4) represents simple exponential relaxation, as predicted from the Bloch equations. In this case, every ^{13}C site has the same relaxation rate. In diamond, this limit occurs if spin diffusion among the ^{13}C nuclei is fast compared with the rate at which an individual ^{13}C nucleus relaxes as a result of a neighboring paramagnetic site. If the situation is reversed, poor communication among the ^{13}C nuclei requires that each relaxes

directly with a neighboring paramagnetic site. Since there is a distribution of ^{13}C to paramagnetic site distances, a dispersion of spin-lattice relaxation rates results. Fortunately, integration over all possible rates, with appropriate assumptions, simplifies to equation (4) with $x = 0.5$.¹³

An excellent consideration of influence of direct ^{13}C relaxation to paramagnetic defects in comparison to spin diffusion rates in diamond is provided by Hoch et al.¹² Unfortunately, both limits as well as mixed behavior are possible. Spin diffusion is slowed when no ^{13}C enrichment is employed and MAS is used. Thus, behavior approaching the $x = 0.5$ limit has been observed for MAS spectra of samples having natural abundance or a 14% ^{13}C enrichment.^{20,21} In contrast, pure exponential behavior ($x = 1.0$) is observed in static spectra of more highly enriched (22%) samples.¹⁶ Analysis of spin diffusion rates as a function of enrichment suggests that paramagnetic centers are distributed uniformly in polycrystalline CVD diamond films, rather than being localized at grain boundaries.¹⁴

Short spin-lattice relaxation time constants have been reported for both ^1H and ^{19}F bonded to diamond. These fast rates suggest paramagnetic centers contribute to spin-lattice relaxation and are further enhanced by rapid spin diffusion among these clustered, high-gyromagnetic ratio nuclei. For ^1H , room temperature T_1 values are in the range of 5 ms to 1 s.^{8,9,21} These values increase after annealing CVD diamond at 500–750 °C suggesting passivation of paramagnetic centers.⁹ The relaxation appears nonexponential, but exact determination of x [see equation (4)], involves a large degree of uncertainty due to the low signal levels available.^{9,21,23} Also, caution must be applied in directly interpreting x , since multicomponent relaxation, motion, and, in the case of ^{19}F , CSA can also lead to nonexponential relaxation. For ^{19}F , nonexponential spin-lattice relaxation with a time constant of ~ 0.5 s has been observed for two samples at room temperature.²³ The ^{19}F T_1 increases as the temperature is lowered to 150 K, but remains fixed upon further decreasing the temperature to 100 K. This behavior is consistent with changes in the static ^{19}F lineshape, indicating motion is occurring at room temperature.

1 INTRODUCTION

Soon after the first observations^{1,2} of nuclear magnetic resonance (NMR) in condensed matter it became clear that this new experiment had promising potential for the measurement and study of atomic transport. Two of the early questions asked about nuclear spin systems were: ‘How does a spin system reach the temperature of the surrounding “lattice”’, and ‘How long does it take to reach this thermal equilibrium?’. Here, the term ‘lattice’ is used to represent all the other degrees of freedom of the material, be it a solid or liquid, containing the spin system. In his phenomenological equations describing the interaction between the nuclear spins and applied static and time-dependent magnetic fields, Bloch³ identified the spin–lattice, or longitudinal, relaxation time T_1 , and the spin–spin, or transverse, relaxation time T_2 . In the presence of a large constant magnetic field, the difference between the instantaneous nuclear spin system’s magnetization and its equilibrium magnetization decays exponentially with the time constant T_1 , while T_2 is the time constant for exponential decay of the magnitude of the coherent component of the magnetization transverse to the large field.

Only 2 years after the publications of discovery of NMR, the first comprehensive description of the relationship between the nuclear spin relaxation rates and atomic motion came in the definitive paper of Bloembergen, Purcell, and Pound,⁴ which identified the relationship between the relaxation rates T_1^{-1} and T_2^{-1} and the modulation of the nuclear dipolar interactions caused by diffusive motion. They showed that each rate could be expressed by a linear combination of spectral density functions evaluated, for like nuclei, at the Larmor frequency and at twice that frequency. Each such function was expressed as the Fourier transform of pair correlation functions for interacting nuclear dipole moments. There are two distinct classifications of NMR experiments used to measure fundamental parameters of translational diffusion of atoms or molecules in solids; both are associated with spin system relaxation times.

The first technique is the measurement of the dependence of relaxation times upon temperature and the Larmor precession frequency. These measurements may be analyzed to yield

the temperature dependence of the mean residence time τ_d of the diffusing entity on a lattice site. The second is the measurement at one temperature of the attenuation of the spin echo in the presence of applied magnetic field gradients, from which the tracer diffusion coefficient D is deduced. The first method relies on having good theoretical understanding of the relationship between the mean residence time, the Larmor frequency and the measured relaxation time. The second technique is simpler theoretically, since it relies only on the assumption that the solution to the diffusion equation holds for the spin system, and it yields the diffusion coefficient directly. A disadvantage of the second technique is that it is more difficult and limited experimentally. It also requires higher diffusivity than does the measurement of some relaxation times.

This use of NMR to measure D directly was suggested by Hahn.⁵ Some kind of atomic or molecular label is needed to measure the diffusion coefficient. In Hahn’s proposal, the atom’s position along a particular direction was effectively labeled by making its Larmor frequency linearly dependent upon position through application of a uniform gradient of the magnitude of the applied magnetic field. With a very small gradient, the precession frequency of each spin is essentially constant. This constancy makes the spin echo^{5,6} experiments possible with echo attenuation limited only by the decay due to T_2 . When diffusion occurs in a sufficiently strong gradient, diffusive motion of each spin makes its precession frequency unpredictably time dependent, so that at the time of echo formation the accumulated disorder in the phases of spins in the transverse plane causes a spin echo attenuation given by⁶

$$S(t)/S(0) = \exp(-t/T_2 - \frac{1}{12}\gamma^2 G^2 t^3 D) \quad (1)$$

where γ is the nuclear magnetogyric ratio, G is the magnitude of the applied magnetic field gradient, τ is the time between the first and second rf pulses, and $t = 2\tau$. Echo attenuation may be measured as a function of G , and the resulting data are analyzed to determine D . The measured D is the tracer diffusion coefficient because the effect of the applied magnetic field gradient is to produce a nearly zero gradient in the chemical potential of the atoms in the system. As noted by Carr and Purcell,⁶ ‘A more innocuous label would be difficult to imagine’.

In terms of the tracer correlation factor f_t ($0 < f_t \leq 1$) and the step length l , D for a crystalline solid is given by

$$D = f_t l^2 / 6\tau_d \quad (2)$$

From independent determinations of τ_d (from relaxation times) and D , the product, $f_t l^2$, can be determined and used to test models for diffusion paths in the solid. For such detailed study, accurate theory for the relationships between relaxation rates and mean residence times are needed and have been calculated for common crystal structures. With these tools at hand, step lengths have been determined, and mixed monovacancy and divacancy diffusion mechanisms and effects of interactions between diffusing atoms have been identified; these topics are discussed below. Sophisticated pulsed gradient techniques have greatly extended the possibilities for measuring D in solids, and some of their applications are presented.

This review is presented in three parts, with the use of relaxation rates in Section 2, measurements of D in Section 3, and applications of these two in Section 4.

2 SPIN RELAXATION AND DIFFUSION

2.1 Introduction

Bloembergen, Purcell, and Pound⁴ (BPP) identified the nuclear dipolar coupling as a strong interaction for inducing spin relaxation. The interaction between two nuclear moments having spins I and S ,

$$\hat{\mathcal{H}}_D = \frac{\hbar^2 \gamma_I \gamma_S}{r_{IS}^3} \left[\hat{\mathbf{I}} \cdot \hat{\mathbf{S}} - \frac{3(\hat{\mathbf{I}} \cdot \mathbf{r}_{IS})(\hat{\mathbf{S}} \cdot \mathbf{r}_{IS})}{r_{IS}^2} \right] \quad (3)$$

varies in time as the internuclear vector $\mathbf{r}_{IS}$ changes because of the diffusive motion of one or both atoms. BPP described how that motion produced Fourier components of fluctuating dipolar fields at the precession frequencies and their sum and difference frequencies needed to induce spin transitions of one or both spins. Transitions in which both spins flip or one spin flips are driven by the raising and lowering operators $\hat{I}^+$, $\hat{I}^-$, S^+ , or S^- , implicitly contained in equation (3). Therefore, Fourier components which drive spin lattice relaxation of the I spin system are ω_{0I} , $2\omega_{0I}$, $(\omega_{0I} + \omega_{0S})$, and $(\omega_{0I} - \omega_{0S})$, where ω_{0I} and ω_{0S} are the resonant frequencies of the I and S spin systems, respectively. General theory of spin system relaxation is available.^{7,8}

For nuclei with $I > \frac{1}{2}$, the nuclear electric quadrupole interaction may, for the same reasons, be an effective relaxation mechanism. Here, atomic motion modulates the electric field gradient,⁹ and in some circumstances, the quadrupolar mechanism is stronger than magnetic dipolar relaxation. However, for measuring parameters of diffusion, utilization of the dipolar mechanism is, when possible, usually preferred because of high uncertainties in the knowledge of electric field gradients in the solid of interest.

As noted above, for accurate analysis of relaxation data, what is needed are accurate calculations, specific to each crystal structure, that relate relaxation rates to a characteristic diffusion parameter, i.e. the mean residence time of the diffusing atom on a crystal site. Relaxation rate theories are calculated in the weak or the strong collision regime. In the strong collision regime, the dipolar correlation time τ_d is greater than the thermal mixing time τ_m for the spin system. τ_m is the characteristic time needed for the Zeeman spin reservoir to come to a common spin temperature with the dipole spin reservoir.¹⁰ This process requires that the Zeeman field be smaller than characteristic dipolar fields, which is a relevant issue in the rotating coordinate system. The book by Goldman¹¹ treats the spin temperature concept in detail. Comments on strong collision experiments are reserved here until after the presentation of weak collision theory.

Weak collision theory applies when the Zeeman field is much larger than the characteristic dipolar field. In this regime $\tau_d \ll \tau_m$. This theory applies to many spin systems and temperatures where (depending upon the magnitude of γ) $\tau_d < 10^{-5}$ s, but strong collision theory extends to slower motion where 10^{-5} s $< \tau_d < 10^{-1}$ s.

2.2 Weak Collision Theory

The spectral density functions are defined by^{7,8}

$$J^{(q)}(\omega) = 2 \int_0^\infty G^{(q)}(t) \cos(\omega t) dt \quad (4)$$

where $G^{(q)}(t)$ is an ensemble average correlation function for the spatial coordinates of the dipolar interaction, and

$$G^{(q)}(t) = \sum_j \overline{F_{ij}^{(q)}(0) F_{ij}^{(q)*}(t)} \quad (5)$$

where the bar indicates the ensemble average. The functions $F_{ij}^{(q)}(t) = d_q Y_{2q}(\Omega_{ij})/r_{ij}^3$ are the dipolar interactions between spins i and j separated by $(r, \Omega)_{ij}$ at time t , and where $Y_{2q}(\Omega)$ are the normalized spherical harmonics having the z axis along the applied magnetic field, $\mathbf{B}_0$. The d factors are: $d_0^2 = (16\pi/5)$, $d_1^2 = (8\pi/15)$, and $d_2^2 = (32\pi/15)$. The spin operators have been incorporated in the expressions for the relaxation rates,^{7,12,13} given here for identical (like) spins:

$$\frac{1}{T_1} = R_1 = \frac{3}{2} \gamma^4 \hbar^2 I(I+1) [J^{(1)}(\omega_0) + J^{(2)}(2\omega_0)] \quad (6)$$

$$\frac{1}{T_{1\rho}} = R_{1\rho} = \frac{3}{8} \gamma^4 \hbar^2 I(I+1) \times [J^{(0)}(2\omega_1) + 10J^{(1)}(\omega_0) + J^{(2)}(2\omega_0)] \quad (7)$$

$$\frac{1}{T_2} = R_2 = \frac{3}{8} \gamma^4 \hbar^2 I(I+1) \times [J^{(0)}(0) + 10J^{(1)}(\omega_0) + J^{(2)}(2\omega_0)] \quad (8)$$

where $T_{1\rho}$ is the spin-lattice relaxation time in the rotating frame¹² and ω_1 is the precession frequency in the rotating field $\mathbf{B}_1$. The correlation functions are given by:¹⁴

$$G^{(q)}(t) = d_q^2 \sum_{\alpha, \beta} \frac{Y_{2q}^*(\Omega_\alpha)^*}{r_\alpha^3} \frac{Y_{2q}(\Omega_\beta)}{r_\beta^3} P(\mathbf{r}_\alpha, \mathbf{r}_\beta, t) \quad (9)$$

where $P(\mathbf{r}_\alpha, \mathbf{r}_\beta, t)$ is the probability of a pair of spins being separated by $\mathbf{r}_\beta$ at a time t given that they were separated by $\mathbf{r}_\alpha$ at time zero, and $P(\mathbf{r}_\alpha, \mathbf{r}_\beta, t)$ is determined by the diffusive motion in the solid. The correlation function decays with a characteristic time τ_c , which for translational diffusion should be approximately the mean residence time. The above expressions apply directly to a single crystal, but can also be averaged over all orientation angles for polycrystalline samples.

It is convenient to express the spherically averaged rates in terms of a single dimensionless spectral function $F(\omega\tau_c)$, which applies to any spin transition (parameter q). Equations (6)–(8) then become (for like spins only):

$$\frac{1}{T_1} = R_1 = \frac{2}{3} M_{II}^2 \tau_c [F(\omega_0\tau_c) + 4F(2\omega_0\tau_c)] \quad (10)$$

$$\frac{1}{T_{1\rho}} = R_{1\rho} = \frac{1}{3}M_{II}^2\tau_c[3F(\omega_1\tau_c) + 5F(\omega_0\tau_c) + 2F(2\omega_0\tau_c)] \quad (11)$$

$$\frac{1}{T_2} = R_2 = \frac{1}{3}M_{II}^2\tau_c[3F(0) + 5F(\omega_0\tau_c) + 2F(2\omega_0\tau_c)] \quad (12)$$

where

$$M_{II}^2 = (\mu_0/4\pi)^2 \gamma^4 \hbar^2 I(I+1) \sum_i r_i^{-6} \quad (13)$$

is, here, the dipole second moment for like spin interactions only.

2.2.1 The BPP Model

A simple assumption of an exponential decay was made by BPP for $G^{(q)}(t)$:

$$G^{(q)}(t) = G^{(q)}(0) \exp\left(-\frac{t}{\tau_c}\right) \quad (14)$$

It follows that the spectral density has the form

$$J^{(q)}(\omega) = \frac{G^{(q)}(0)2\tau_c}{[1 + (\omega\tau_c)^2]} \quad (15)$$

Torrey¹⁵ pointed out that, for like spins, the *relative* motion of spins contributes to the decay of $G^{(q)}(t)$, and therefore $\tau_c = \tau_d/2$. The relatively simple BPP form of $J^{(q)}(\omega)$ has made it a very useful, though approximate, model for analysis of data. In the low frequency, or short correlation time, regime ($\omega\tau_d \ll 1$), $J^{(q)}(\omega)$ is essentially independent of frequency, and for like spins $J^{(q)}(\omega) \approx G^{(q)}(0)\tau_d[1 - (\omega\tau_d/2)^2]$. At high frequencies, or long correlation times $\omega\tau_d \gg 1$, and again for like spins, $J^{(q)} \approx 4G^{(q)}(0)/(\omega^2\tau_d)$.

The low-frequency behavior of the BPP model is inconsistent with the solution to the diffusion equation when applied to calculation of $J^{(q)}(\omega)$, which for solids¹⁶ or liquids¹⁷ is

$$J^{(q)}(\omega) \approx J^{(q)}(0)[1 - c_1\omega^{1/2}] \quad (16)$$

where $J^{(q)}(0) \propto \tau_d$ and c_1 is a constant, different for solids than for liquids. In fact, c_1 specifically depends on D , so that in principle D could be determined from the frequency dependence of $J^{(q)}(\omega)$ in the short correlation time regime.¹⁶ [For two-dimensional diffusion¹⁶ there is a much stronger frequency dependence at $\omega\tau_d \ll 1$. Here, $J^{(q)}(\omega) \approx c_2\tau_d \ln(\omega)^{-1}$, where c_2 is dependent upon D and the structure of the solid.] In the very low and high frequency limits, accurate calculations show that $J^{(q)}(\omega)$ is proportional to τ_d and to $(\omega^2\tau_d)^{-1}$, respectively, as in the BPP model, but the constants of proportionality in the BPP model can be in error^{16,18} by up to a factor of 3. For thermally activated diffusion $\tau_d = \tau_0 \exp(E_a/RT)$, where E_a is the activation energy (per mole) for diffusion. It is usually convenient experimentally to hold the NMR frequency constant and vary the temperature. In such an experiment a graph of the relaxation rate, R_1 versus $(1/T)$, would have slope $+(E_a/R)$ at very high temperatures and

Figure 1 Relaxation rate (in arbitrary units) as a function of $\omega_0\tau_d$ for R_1 , $R_{1\rho}$ and R_2 in the BPP model with $\omega_0 = 500 \omega_1$

$-(E_a/R)$ at low temperatures. On such a graph the maximum of R_1 in the BPP model occurs for a system of like spins, at $(\omega\tau_d) = 1.23$. Although the BPP model is an approximation and not specific to any crystal lattice, it is highly regarded for its ease in applicability and its utility. It is seen in the next section that the errors noted above may be significantly reduced if it is assumed that for like spins $\tau_c = \tau_d$. The dependences of R_1 , $R_{1\rho}$, and R_2 , upon $\omega\tau_d$ in the BPP model are shown in Figure 1. On the low-temperature side of the peak in R_1 , the transverse rate, $R_2 \propto \tau_d$. Using this relationship, Hultsch and Barnes¹⁹ measured the pressure dependence of T_2 of ^7Li and ^{23}Na in solid lithium and sodium, respectively, and determined the activation volumes for self-diffusion in these solids.

2.2.2 Lattice-Specific Models

In many solids, translational diffusion is enabled by vacancies, (empty lattice sites) in the solid. Only atoms next to a site vacancy can move. For most solids, vacancies must be thermally activated. Typically, vacancy concentrations are very small, increase strongly with temperature, but reach fractional concentrations of only about 10^{-4} to 10^{-3} near the melting point. When a vacancy encounters an atom the atom can move, but its motion during the encounter is not random in that it has a significant probability of jumping back to take the place of a vacancy immediately after it has exchanged sites with it. The effect of this correlated motion²⁰ on the NMR spectral density is distinguishable from an uncorrelated random walk process that would occur with low atom concentration on an otherwise empty lattice. The interstitialcy mechanism has also been considered in lattice-specific calculations.

High vacancy concentrations are characteristic of a number of systems, such as hydrogen in metals and fast ionic conductors. For example, in the α' phase of the VH_x , NbH_x , and TaH_x systems, hydrogen atoms occupy the tetrahedral interstitial sites and the solubility of hydrogen atoms in this phase ranges from $x = 0$ to about 0.7, depending on the host metal. Therefore, there is interest in knowing $J^{(q)}(\omega, \tau_d)$ for the full range of atomic concentration, c . Figure 2 shows a plot

Figure 2 Angular average of the spin-lattice relaxation rate (in arbitrary units), divided by c , as a function of $y = \omega_0\tau_d/2$ for like spins on the simple cubic lattice. (---) The BPP model. (—) Lattice-specific models for atom concentrations, from left to right: $c \rightarrow 1$, 0.99, 0.90, 0.70, 0.50, and $c \rightarrow 0$, respectively. (Reproduced by permission of IOP Publishing Ltd from C. A. Scholl, *J. Phys. C: Solid State Phys.*, 1988, **21**, 319)

of R_1 versus $(\omega\tau_d/2)$ calculated from lattice-specific models¹⁴ for the simple cubic lattice. It can be seen in Figure 2 that letting $\tau_c = \tau_d$ in the BPP model moves the BPP curve a factor of 2 to the left and into better agreement with the others. Many calculations of $J^{(q)}(\omega, \tau_d)$ must be done numerically.

The relationships between relaxation rates and the mean residence time, τ_d have been calculated specifically for the more common crystal structures, for example: simple cubic (s.c.); body-centered cubic (b.c.c.); and face-centered cubic (f.c.c.). These relationships do indeed differ perceptibly from one lattice to another. It is known that the dependence of R_1 upon τ_d for a given lattice changes with the microscopic diffusion mechanism, but that these differences are small. Measurements of high precision on spin systems with very well understood relaxation mechanisms are needed before one can hope to use experimental data to rule out a contending microscopic mechanism.

The first lattice-specific relaxation rate theoretical calculations for R_1 and R_2 were made by Torrey¹⁵ and Resing and Torrey.²¹ In these calculations, nuclear dipoles were assumed to move by an uncorrelated random walk by nearest neighbor jumps through the lattice. The average of relaxation rates over all crystalline directions were approximated by the use of an isotropic diffusion model. Relaxation rates were calculated numerically for like spins only; their most accurate results are presented in Resing and Torrey²¹ in tabular form for the b.c.c. and f.c.c. lattices. At fixed frequency, R_1 reaches a maximum at $\omega\tau_d = 1.06$ and 1.04 for the f.c.c. and b.c.c. lattices, respectively. Because of the assumption of uncorrelated motion, these results would be expected to be applicable at low concentrations of atoms on a crystal lattice, or sublattice.

Before it appeared in print, the Torrey model was applied to analyze data in the first comprehensive set of pulsed NMR experiments²² measuring effects of diffusion on NMR relaxation rates in alkali metals. Holcomb and Norberg²² convincingly demonstrated the applicability of NMR to the study of diffusion in solids. Their most extensive data were

Figure 3 Plot of $\omega_0\tau_d/2$, where $\tau = \tau_d$, against $10^3/T$ for ^7Li in solid lithium. Values of τ were obtained from analysis of R_1 data at 3 MHz using the Torrey theory. The slope is $13.2 \text{ kcal mol}^{-1} = 55.2 \text{ kJ mol}^{-1}$. (Reproduced by permission of The American Physical Society from D. F. Holcomb and R. E. Norberg, *Phys. Rev.*, 1955, **98**, 1074)

from ^7Li with temperature dependence of T_1 measured at 3, 6, 9, and 15 MHz. ^7Li data at 3 MHz were analyzed by trying both the BPP and the Torrey theory. The better fit to the data, shown in Figure 3 came from Torrey theory for the b.c.c. lattice, and from it they found that $E_a = 55.2 \pm 2 \text{ kJ mol}^{-1}$.

Sholl^{23,24} and Wolf²⁵ addressed the random walk problem without the approximation of isotropic diffusion. Both took the discrete nature of the lattice into account for both single and polycrystalline materials. The papers of Barton and Sholl,²⁶ provide good perspective on the random walk model and include tables that conveniently allow calculation of R_1 , $R_{1\rho}$, or R_2 , for any product of $\omega\tau_d$ in s.c., b.c.c., or f.c.c. lattices. These improved calculations have, for like spins in a polycrystalline sample, the maximum in R_1 occurring at $\omega\tau_d = 1.04$, 0.99, and 0.92 for f.c.c., b.c.c., and s.c. lattices, respectively.

While few real systems were expected to have atoms diffusing by random walk, these lattice-specific calculations were still important in the development of the theory. The shape of the R_1 versus τ_d curve for random walk fit the data better than the shape of the BPP curve did. A second improvement to the random walk came with the mean field model²⁷ which accounted for the effects of site blocking. That is, it excluded the possibility of having two atoms on the same site. The mean field theory is exact where a single jump for a pair of spins is relevant, in the low-temperature (high-frequency) limit, except where the fractional atom concentration is $c \rightarrow 1$. It is also exact in the dilute

limit as $c \rightarrow 0$, and the model was expected to be a good approximation for most concentrations except²⁶ as $c \rightarrow 1$. In the mean field model, for like spins in a polycrystalline sample, the maximum in R_1 occurs at $\omega\tau_d = 0.95, 0.89$, and 0.77 for f.c.c., b.c.c., and s.c. lattices, respectively.

2.2.3 Monovacancy Diffusion

Diffusion enabled by vacancies at extremely low concentration is known as ‘monovacancy diffusion’. Wolf²⁸ provided the first relaxation rate theory applicable to this mechanism. At their characteristically low concentration, vacancies move with random walk and atoms are displaced only through encounters with vacancies. Eisenstadt and Redfield²⁹ identified the encounter model and its role in NMR relaxation in their study of diffusion in ionic crystals.

Wolf³⁰ calculated relaxation rates in the encounter model for both the weak and strong collision regimes, and he identified characteristic features of temperature-dependent experimental data that could, in principle, be applied to identify microscopic diffusion mechanisms. He emphasized the valuable information contained in the anisotropy of relaxation rates,^{28,30,32} especially $R_{1\rho}$, for single crystal samples. For polycrystalline or single crystal samples, Wolf et al.³² defined measures of the width and asymmetry of the relaxation peak that were dependent upon the mechanism of diffusion.

A comprehensive series of experiments were performed by Figueroa and Strange and reported with Wolf^{32,33} on the NMR of ^{19}F in pure BaF_2 and crystals doped with K^+ to control F^- vacancy concentrations, or with La^+ to control number of interstitial F^- . This element of control made it possible to determine the activation energies for migration of F^- by vacancies ($E_{\text{mv}} = 59 \text{ kJ mol}^{-1}$) and by interstitials ($E_{\text{mi}} = 74 \text{ kJ mol}^{-1}$). From the pure BaF_2 data (Figure 4), the energy of formation of Frenkel anion pairs ($E_{\text{f}} = 174 \text{ kJ mol}^{-1}$) was determined. Comparison with conductivity data³⁴ showed satisfactory agreement with diffusion parameters obtained by the two techniques. In their analysis of the NMR data, there was clear agreement with the encounter model but not the random walk model. Even though the data appear to have little scatter, especially considering the very high temperatures at which much of it was recorded, the difference between the interstitialcy and monovacancy mechanisms could not be distinguished.

Building upon previous calculations on relaxation rate theory,^{16,35} MacGillivray and Sholl³⁶ improved the accuracy of the encounter model in the monovacancy limit to better than 4% and 1% in the low- and high-frequency regimes, respectively. Their paper contains numerical tables from which spectral densities $J^{(q)}(\omega, \tau_d)$ can conveniently be calculated for s.c., b.c.c., and f.c.c. lattices. From these, more accurate predictions of the width and asymmetry of relaxation rate peaks can be made. In the monovacancy limit, the peaks in the spin-lattice relaxation rate R_1 for like spins occur at³⁵ $\omega\tau_d = 0.57, 0.51$, and 0.42 for the f.c.c., b.c.c., and s.c. lattices, respectively. All these peaks in R_1 occur at significantly lower values of $\omega\tau_d$ than in the random walk or the mean field models. This means that if NMR data for R_1 or $R_{1\rho}$ from a solid having monovacancy diffusion were analyzed with the random walk, mean field, or the BPP models, the deduced τ_d at temperatures near maximum relaxation rates would be too large by at least 67% for the first two, and by more than

Figure 4 Relaxation times plotted against $10^3/T$ for ^{19}F in a pure BaF_2 single crystal. ($\square$) T_1 taken at 10 MHz; ($\circ$, $\bullet$, Δ) $T_{1\rho}$, $B_1 = 1.2 \times 10^{-3} \text{ T}$, for three different crystal orientations; ($\blacktriangle$) $T_{1\text{Dipolar}}$; ($\blacksquare$) T_2 . Details on crystal orientations may be found in Figueroa et al.³³ (Reproduced by permission of The American Physical Society from D. R. Figueroa, J. H. Strange, and D. Wolf, *Phys. Rev. B*, 1979, **19**, 148)

100% for the BPP model. But the error in the activation energy would probably be very small for the first two models because they give essentially the same shape for the relaxation peaks. However, since the peak is narrower in the BPP model, the activation energy derived from its use could be systematically too small by an amount that depends upon the range of temperature over which data were available (see Section 2.2.5).

2.2.4 Models for Arbitrary Concentrations

In 1978, Fedders and Sankey¹⁸ published their multiple scattering theory for the s.c. lattice using a reciprocal space formalism that can be applied to any concentration from $c = 0$ to nearly the monovacancy limit. They published their numerical results for the spectral densities in the low- and high-frequency limits for $c = 0$ to $c \rightarrow 1$ in steps of $\Delta c = 0.2$. While they gave no numerical tables for the spectral densities at arbitrary $\omega\tau_d$, they offered to supply tables of T_1 versus $\omega\tau_d$ upon request. It is pointed out that the lattice-specific relaxation function (Figure 5) approaches its high- and low-temperature limits more gradually than the BPP model does. Results for the f.c.c. lattice were reported in a later paper.³⁷ An interesting product of their formalism is a simple analytic

Figure 5 Angular average of spin-lattice relaxation time (in arbitrary units) for like spins on the s.c. lattice as a function of $\omega_0\tau_d$ calculated for the multiple scattering theory with atomic concentration $c = 0.85$. (---) Asymptotic limits for $\omega_0\tau_d$ sufficiently large and small; they show how gradually the curve approaches each line. (Reproduced by permission of The American Physical Society from P. A. Fedders and O. F. Sankey, *Phys. Rev. B*, 1978, **18**, 5938)

expression (accurate to about 1%) for the tracer correlation factor for atoms at concentration c in a simple cubic lattice:

$$f_t = 0.7882[1 + 0.1059(6c - 4)/(2 - c)] \quad (17)$$

Fedders³⁸ also considered the effect that interactions between mobile atoms would have on the dipolar relaxation mechanism. These interactions are more likely to be important in systems having intermediate concentrations of diffusing atoms (with number of vacancies exceeding 10% of the number of lattice sites), as in metal hydrides. At short distances, the H-H interaction is repulsive, and in some metals, (for example, the group V transition metals) it is sufficiently strong to prevent simultaneous occupation of nearest neighbor interstitial sites. In the BPP model, one would be tempted to compensate for this interaction by simply removing nearest neighbor terms from the lattice sums contained in calculating the second moment of the hydrogen spin system. Doing this underestimates the dipolar interaction strength in the low-frequency (high-temperature) regime because here the motions of atoms further from each other than the nearest neighbor positions are the most effective in inducing spin transitions. For this motion short-range repulsive reactions are irrelevant.³⁸ On the high-frequency (low-temperature) side of the relaxation rate peak, single steps of atoms account for the decay of the pair correlation function and the reduction of the second moment is a good approximation³⁸ to the effects of the above repulsive interaction.

2.2.5 Monte Carlo Simulations

For any crystal structure, the pair correlation functions $G^{(q)}(t, \tau_d)$ can be computed numerically by simulating motion with the Monte Carlo technique. Bustard³⁹ established an s.c. lattice having 8000 sites (20 lattice constants on each side) and assumed periodic boundary conditions. Using the Monte Carlo

Figure 6 Angular average of spin-lattice relaxation rates as a function of $\omega_0\tau_d$, as calculated for like spins from simple cubic lattice theories. ($\square$) Monovacancy encounter model;¹⁰ ($\bullet$) random walk model;²⁶ ($\triangle$) vacancy concentration, $c_v = 0.15$.¹⁸ (—) Monte Carlo for $c_v = 0.15$. (Reproduced by permission of The American Physical Society from L. D. Bustard, *Phys. Rev. B*, 1980, **22**, 1))

technique he calculated numerically T_1^{-1} versus $\omega\tau_d$ for like spins on this s.c. lattice with vacancy concentrations, $c_v = 3.75 \times 10^{-4}$, 0.15, 0.225, and 0.90, and published the appropriate tables for these concentrations. The Monte Carlo results are in substantial agreement with multiple scattering theory¹⁸ for $c_v = 0.15$ (Figure 6) and with mean field theory²⁶ for $c_v = 0.90$. A difficulty in the Monte Carlo calculations is their inaccuracy in the low-frequency regime. Bustard³⁹ dealt with this by making a least-squares fit to $G^{(q)}(t, \tau_d)$ with a sum of decaying exponentials. This substitution facilitated making the Fourier transform to $J^{(q)}(\omega, \tau_d)$ but, since the long time tails of the exponential decay curves decay faster than the actual¹⁶ $t^{-3/2}$ form of the tail of $G^{(q)}(t, \tau_d)$, Bustard's Monte Carlo magnitudes of R_1 and $R_{1\rho}$ were too small where $\omega\tau_d \ll 1$. Nevertheless, the calculations were accurate enough for R_1 data to be analyzed at two NMR frequencies in order to obtain the temperature dependences of τ_d for ^1H in $\text{TiH}_{1.55}$ and $\text{TiH}_{1.70}$, where $c_v = 0.225$ and 0.15 on the interstitial s.c. lattice, respectively. These results for τ_d were combined with direct NMR measurements⁴⁰ of the diffusion coefficient D using the pulsed field gradient technique in the stimulated echo experiment, so that the mean squared jump length l^2 could be determined from $D = f_t l^2 / (6\tau_d)$. It was found that hydrogen atoms jump to their nearest neighbor sites and not to their third nearest neighbor sites as had been found theoretically to be feasible.⁴¹ Similar sets of experiments have recently been done for the isomorphic system ZrH_x ,⁴² analyzing R_1 data with more recent Monte Carlo calculations⁴³ for τ_d , and reaching the same conclusion.

Faux et al.⁴³ made Monte Carlo calculations for like spins moving according to the simple hopping model on f.c.c., b.c.c. and s.c. lattices. They fitted their numerical calculations of $J^{(q)}(\omega, \tau_d)$ in the low- and high-frequency limiting cases to the corresponding expected frequency dependences calculated earlier by Sholl.¹⁶ This fitting also checked the accuracy of their Monte Carlo numerical procedures.⁴³ Numerical tables provide spectral densities and R_1 at many selected values of $\omega\tau_d$ for concentrations c approaching 0, 0.5, 0.7, 0.9, and 0.99. For $c \leq 0.4$, application of mean field theory might be an

acceptable and convenient approximation, since its difference from the Monte Carlo results is quite small.⁴³

Because use of numerical tables is not as convenient as an analytic expression (such as that for the BPP model) in fitting experimental data, analytic approximations to the numerical tables given by Faux et al.⁴³ for intermediate concentrations, by Barton and Sholl²⁶ for mean field theory, and by MacGillivray and Sholl³⁶ for monovacancy diffusion have been developed by Sholl.¹⁴ Faux et al.⁴³ and Sholl¹⁴ provide an overview of the dependences of the relaxation rates upon atom concentration on the f.c.c., b.c.c., and s.c. lattices from $c \rightarrow 0$ to $c \rightarrow 1$. Figure 2 shows R_1 versus $\omega\tau_d/2$ for the full range of concentration on a simple cubic lattice plotted from the analytic expressions given by Sholl¹⁴ and, for comparison, the BPP model. It is seen here, and is apparent for all cubic lattices, that the relaxation peak is narrower in the BPP model than for any concentration of the lattice-specific models. There is little concentration or model dependence in the maximum relaxation rates shown in Figure 2. For all the lattice-specific relaxation rate curves, their peaks are located at significantly lower values of $\omega\tau_d$ than for the BPP model (using $\tau_c = \tau_d/2$). It can be seen in Figure 7 that

Figure 7 The value of $(\omega_0\tau_d)_{\max}$ at the maximum of the R_1 versus $\omega\tau_d$ curve, plotted against atom concentration c for a polycrystalline b.c.c. lattice. The $(\omega_0\tau_d)_{\max}$ values are normalized to the mean field theory value of 0.89. The point at $c = 1$ is for the monovacancy limit. The bar is the estimated error of the Monte Carlo results. The points for the f.c.c. and s.c. lattices lie above and below these points, respectively. On this graph, the points for the BPP model would be at 1.38, independent of c . (Reproduced by permission of IOP Publishing Ltd from D. A. Faux, D. K. Ross, and C. A. Sholl, *J. Phys. C: Solid State Phys.*, 1986, **19**, 4115)

Figure 8 (---) $\tau_d = \tau_{\text{BPP}}$, obtained by analyzing the R_1 relaxation results of the mean field theory using the BPP model. The horizontal axis shows τ_d in the mean field theory, and $(\omega_0\tau_d)_{\max}$ is approximately centered. The solid line has the 'correct' slope. In the limits of large and small τ_d , the two lines are parallel, but over the region shown, the average slope of the dashed line is seen to be the smaller one. (Reproduced by permission of Sci-Tech Publications from C. A. Sholl, *Diffus. Defect Data, Solid State Data A, Defect Diffus. Forum*, 1993, **95–98**, 91)

the value of $\omega\tau_d$ at the peak decreases monotonically from the $c = 0$ limit to the $c = 1$ limit, with most of the change coming between $c = 0.5$ and $c = 1.0$. Because the value of $\omega\tau_d$ at the peak may be used to set the absolute values of the determinations of τ_d from experimental R_1 data, Figure 2 is useful for estimating the relative error resulting from application of an inappropriate model. The activation energies determined by application of the BPP model should be accurate if there are experimental data extending far into the wings of the relaxation peak. However, often the data are most accurate or only available near the peak where there is relatively less competition from other relaxation mechanisms. In this regime, the narrowness of the peak in the BPP model means that if it were used to analyze data obtained with a lattice-specific model, the resulting values of τ_d (shown as τ_{BPP} in Figure 8) might be interpreted in terms of an activation energy that would be too small. The resulting systematic error in E_a could exceed 10%.⁴⁴

2.2.6 Quadrupolar Relaxation Mechanisms

As noted earlier, nuclear electric quadrupolar interactions may be an effective mechanism for spin relaxation where the interaction is modulated by atomic motion. Its utilization for the study of diffusion is more complicated than the dipolar mechanism because: (1) the electric field gradient (EFG) might be unknown; and (2) the spin system's recovery might be multiexponential. Lack of knowledge of the magnitude of the EFG might be acceptable, since it mainly affects the magnitude of spin–lattice relaxation rates, but it might have a temperature dependence strong enough to complicate data interpretation. The recovery through spin–lattice relaxation will be a single exponential⁷ if the spin $I = 1$, if the motion is so fast that $\omega_0\tau_d \ll 1$, or if the dipolar interaction can maintain a spin temperature in the spin system.¹⁰ Otherwise, the recovery is the sum of exponentials the number of which depends upon I .⁴⁵ If the spin system has a static quadrupole interaction,

establishment of a spin temperature is unlikely outside of thermal equilibrium with the lattice.

Without a static quadrupole interaction, it is likely that the dipolar interactions within the spin system can maintain a spin temperature during recovery. If so, the recovery occurs with the relaxation rate^{7,10}

$$\frac{1}{T_{1Q}} = R_{1Q} = C_Q [J_Q^{(1)}(\omega_0) + J_Q^{(2)}(2\omega_0)] \quad (18)$$

where

$$C_Q = (9/160)(eQ/\hbar I)^2(2I + 3)/(2I - 1) \quad (19)$$

and the dynamic EFG is contained in the spectral densities, $J_Q^{(i)}(\omega_0)$. If the dynamic EFG is due to point charges, as in ionic compounds, the spectral densities will depend upon normalized spherical harmonics as do those for dipolar interactions. But the quadrupolar spectral densities may differ from the dipolar because of the potential importance of three particle correlation functions in many solids.⁴⁶ A difference in principle is that the $J_Q^{(2)}(2\omega_0)$ term in quadrupolar relaxation corresponds to $\Delta m = \pm 2$ of one spin, but in dipolar relaxation it means $\Delta m = \pm 1$ for a pair of spins. If a spin temperature is not maintained during recovery, the recovery is a combination of I exponentials for integral spins and $(I + \frac{1}{2})$ exponentials for half-integral spins.⁴⁵ For a system with a static quadrupole interaction, the mix of exponentials is expected to be similar to that with no static interaction except that the spectral density functions would have arguments different from ω_0 and $2\omega_0$. The mix would depend upon the initial conditions of the spin system at the start of the recovery as established by the rf pulse sequence used and the energy levels to which it was applied. Gordon and Hoch⁴⁵ present results for excitation of the central transition only.

Because of the uncertainties of the magnitude of the dynamic quadrupole interactions, and because static interactions often occur in the less common crystal structures and in disordered solids, very few lattice-specific calculations are available for data analysis. The BPP model is often applied to obtain numerical values of diffusion parameters from these experiments.

2.2.7 Disordered Solids

In disordered solids, such as alloys or glasses, it would be expected that each atom of a given type would have different probabilities for jumping in each of its likely jump directions because of different barrier heights and vibration frequencies. Also, there would be a distribution of site binding energies, and, ignoring other possible effects of the disorder, it is still not obvious how these variations would affect the temperature and frequency dependences of NMR relaxation rates.

It is commonly found experimentally that at fixed frequency, when the relaxation rate due to translational diffusion has been plotted against T^{-1} , the characteristic peak in the rate has a lower magnitude slope on the low-temperature side than on the high-temperature side. In systems where, for example, the mean squared dipolar interaction is known through independent measurement of the second moment of the NMR line, the maximum relaxation rate may be reduced from the rate estimated from the known second moment. These

characteristics may be emulated in the calculation of a mean relaxation rate for a distribution of activation energies where the dependence of R_1 upon E_a follows from its dependence upon τ_d and the Arrhenius relationship:

$$\tau_d = \tau_0 \exp(E_a/RT) \quad (20)$$

Assuming a distribution of activation energies, $g(E_a)$, the mean relaxation rate is

$$\left\langle \frac{1}{T_1} \right\rangle = \int g(E_a) R_1(E_a) d(E_a) \quad (21)$$

There are other models for NMR relaxation in disordered systems. Beckmann⁴⁷ has reviewed many and presented them in a format readily applied to NMR. The question for each is: what is the physical significance of the parameters that would be derived from a fit to NMR relaxation data? McDowell⁴⁸ has applied Monte Carlo techniques to solids disordered with distributions of site energies and, separately, with distributions of barrier height energies. He has found that in the Monte Carlo simulations the observed asymmetry of the relaxation peak occurs with the barrier height distribution but not with the site energy distribution.

The Kohlrausch–Williams–Watts (KWW) model⁴⁷ has seen considerable application. It produces the characteristic asymmetric shape of the relaxation peak and is known as the ‘stretched exponential’ for the form of its correlation function, which is proportional to $\exp[-(t/\tau^*)^{1-n}]$, where $n < 1$. Ngai and Martin⁴⁹ argue that at long times, decay of the correlation function is slowed down due to dynamic correlations among the atoms that arise from their mutual interactions.

Elliot’s diffusion controlled relaxation (DCR) model⁵⁰ has recently been applied to NMR in ionic conducting glasses.⁵¹ The transport mechanism involves the motion of interstitialcies followed by ionic relaxation in the vicinity of a recently arrived interstitial atom. The form of the correlation function can be viewed as a stretched exponential, but the power β to which the time t is raised would be itself time dependent.

No one model is expected to be applicable to all disordered systems, and more than one model might fit the data of one system. What remains to be seen is which models can be convincingly identified with the structure and dynamic processes in glasses. A good test of the applicability of a spin relaxation model is to compare its predictions of the diffusion coefficient of the mobile atom, based on relaxation rate measurements, to an independent set of measurements of D obtained from, for example, NMR pulsed field gradient measurements, or from electric conductivities, preferably in the same temperature range, although this cannot always be realized because of the limitations in measuring low values of D .

2.3 Strong Collision Theory and Experiments

The strong collision regime, defined by Slichter and Ailion,⁵² is characterized by fast thermal mixing between the dipolar and Zeeman energy reservoirs that meets the condition $\tau_m \ll \tau_c$, where τ_m is the mixing time, and $\tau_c = (\tau_d/2)$ for a system of like spins in the solid. This energy exchange cannot occur if $B_1 > B_{D\rho}$, where $B_{D\rho}$ is the measure of the

nuclear dipolar field in the rotating frame. At sufficiently low temperatures, $\tau_m^{-1} \approx \gamma B_{D\rho}$, so that the inequality, $\tau_m \ll \tau_c$ requires that the lattice temperature be below the motional narrowing temperature of the solid.⁸ Under these conditions, Slichter and Ailion find

$$R_{1\rho} = \frac{2(1-p)}{\tau_d} \frac{B_{D\rho}^2}{B_1^2 + B_{D\rho}^2} \quad (22)$$

where p is a parameter which represents the fact that the local field is not completely random after a single atom jump. The important concept in the strong collision regime is that the correlation time is essentially determined by single jumps. In the rotating frame experiment, the relatively high degree of order in the spin polarization, originally along the large applied field in the laboratory frame, becomes transferred to dipolar and Zeeman order in the rotating frame. This order is locally disrupted when an atom jumps to a neighboring site and may be gradually eroded by some other spin-lattice relaxation mechanism. The latter limits $T_{1\rho}$, which puts an upper limit on τ_d that is measurable. In the Slichter and Ailion experiment⁵³ on ^7Li in lithium metal, relaxation by conduction electrons limited observation to temperatures above about 190 K where $\tau_d \leq 1$ s, a very long time in translational diffusion. The values of τ_d obtained in this regime were found to be consistent with those found from T_1 measurements by Holcomb and Norberg.²²

The strong collision theory is lattice specific in that the parameter p must be carefully calculated for each lattice. In their experimental paper,⁵³ Slichter and Ailion derived p for the b.c.c. lattice and found $p = 0.2663$. Of course, $B_{D\rho}$ is also lattice dependent (see *Ultralow Motions in Solids*).

3 DIRECT MEASUREMENT OF DIFFUSION COEFFICIENTS USING MAGNETIC FIELD GRADIENTS

3.1 Introduction

Analysis of measurements of the temperature and frequency dependence of nuclear spin relaxation rates yields the temperature dependence of the mean residence time of atoms in the solid. For a known structure of the solid, and from an assumed or known mechanism of diffusion and its tracer correlation factor, D can be calculated using equation (2). But it is not necessary to rely upon theory to obtain D , because it is directly measurable with NMR from echo attenuation caused by application of uniform magnetic field gradients in a selected spin echo experiment. As noted in Section 1, the field gradient provides the label needed in the measurement of the tracer D . At a coordinate, $\mathbf{r}$, the precession frequency is given by $\omega(\mathbf{r}) = \gamma B_0 + \gamma \mathbf{G} \cdot \mathbf{r}$, where B_0 is the applied magnetic field, $\mathbf{G}$ is the applied gradient, and $\mathbf{G} = \nabla B_z$. Usually only the z component of ∇B_z is applied in measuring D , although the others might be used to measure diffusivity in directions normal to B_0 . (Unless otherwise stated, D is assumed to be isotropic.) In addition to the applied gradient, there is usually a background gradient $\mathbf{G}_0$, which includes the inhomogeneity of B_0 and constant gradients in the sample due to the sample material susceptibility and its shape.

3.2 Application of a Constant Field Gradient

Although it is possible through extraordinary measures to remove the dipolar interaction in solids with multiple pulse techniques, most diffusion measurements are made at temperatures where the dipolar interactions are motionally narrowed. For the Hahn spin echo, the echo attenuation for gradients constant in time, is given by⁶

$$S(t) = 2\tau/S(0) = \exp[-(2\tau/T_2) - \frac{2}{3}\gamma^2 D \tau^3 (\mathbf{G} + \mathbf{G}_0)^2] \quad (23)$$

where τ is the time between the $\pi/2$ and the π rf pulses. At a fixed echo time, the numerical value of D may be obtained from dependence of the echo attenuation upon the magnitude of $\mathbf{G}$. This method is relatively easy to implement especially in application to fluid samples where D is large. For example, for ^1H in water where $D \approx 2 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, and $\tau = 30$ ms, $G \geq 2 \times 10^{-2} \text{ T m}^{-1}$ to attenuate the echo by a factor $1/e$, and it has been assumed that $G \gg G_0$. In solids, where D may be much smaller, considerably larger field gradients would be needed for acceptable echo attenuations.

The need for larger constant gradients presents two experimental problems, beyond the nontrivial ones of gradient coil design and coil cooling, which are: (1) the need for high rf power to provide the larger tipping field in the rotating coordinate system; and (2) the need for broader bandwidth, $\Delta\omega_{\text{rec}}$ for the rf receiver in the NMR spectrometer to accompany the broader spectrum of the spin system being observed. The NMR linewidth will be broadened by the gradient field by approximately $\Delta B \approx GR$, where R is the radius of the sample. Therefore, the tipping field B_1 must be increased as G is increased, and the rf power must increase as G^2 is increased. To avoid having the observed echo shape distorted, $\Delta\omega_{\text{rec}}$ must exceed the spectral width of the spin system observed. An increased $\Delta\omega_{\text{rec}}$ increases the noise observed with the echo and, therefore, reduces the signal-to-noise ratio and increases the accumulation time needed for an acceptable signal-to-noise ratio. These experimental problems are so severe that the constant gradient has not seen much use for solids.

3.3 Application of Pulsed Field Gradients

3.3.1 The Spin Echo Pulsed Field Gradient Experiment

The solution to these problems, turning off the field gradient during rf pulses and during signal accumulation, was proposed by Stejskal and Tanner in their definitive paper⁵⁴ describing the use of pulsed field gradients (PFGs) for the measurement of D . The timing of the gradient pulses in the spin echo experiment is shown in Figure 9 where a gradient pulse of amplitude $\mathbf{G}$ is applied at a time t_1 after the $\pi/2$ pulse and again after the π pulse at a time Δ after the start of the first gradient pulse. The width of each gradient pulse is δ . Using the calculation method of Torrey⁵⁵ and Abragam,⁷ Stejskal and Tanner derived the expression for echo attenuation for their two-pulse PFG:

$$F(t = 2\tau) = \exp\left\{-(t/T_2) - \gamma^2 D [\delta^2 (\Delta - \frac{1}{3}\delta) G^2 + \frac{2}{3}\tau^3 G_0^2 - \delta (t_1^2 + t_2^2 + \delta(t_1 + t_2) + \frac{2}{3}\delta^2 - 2\tau^2) \mathbf{G} \cdot \mathbf{G}_0]\right\} \quad (24)$$

Figure 9 Timing of rf and magnetic field gradient pulses in the PFG spin echo experiment. G is the applied gradient, G_0 is the background gradient, and the spin echo (not shown) occurs at $t = 2\tau$

where $t_2 = 2\tau - (t_1 + \delta + \Delta)$. Other parameters are defined in Figure 9. The G_0^2 term is the usual one for a constant gradient. The $\mathbf{G} \cdot \mathbf{G}_0$ (cross) term arises in the Stejskal and Tanner derivation of $F(t = 2\tau)$. To ignore the G_0 terms, it is necessary that $\delta G \gg \tau G_0$. Under these conditions the cross term is larger than the G_0^2 term, and if G_0 were essentially uniform across the sample, the cross term would make a plot of $\ln F(t = 2\tau)$ versus G^2 nonlinear.

There are stringent requirements for generating the pulsed currents that create the field gradients. The coils and sample must be firmly supported in order to minimize mechanical vibration caused by the large magnetic forces that act on the gradient coils. Since the first pulse defocuses the spins and the second refocuses them, their areas, $G\delta$ must match each other to high precision. For example, at a maximum gradient strength of 0.1 T m^{-1} with a 0.2 cm diameter sample and pulse widths of the order of 10 ms , one pulse gives ^1H spins an angular displacement of more than 10^4 rad. Therefore the matching precision must be better than 10 ppm for reproducible echo amplitudes. Callaghan⁵⁶ recently proposed a sequence to improve this pulse matching.

3.3.2 Background Gradients

The G_0 associated with a very homogeneous applied field B_0 is usually negligible. But in samples that are heterogenous on a small length scale, background gradients can be large. The apparently anomalous rapid transverse decay of the ^7Li spin envelope of liquid lithium was attributed by Zamir et al.⁵⁷ to diffusion in the distribution of background gradients in closely, but randomly, packed spherical lithium particles in oil. Similar effects were observed⁵⁸ in the NMR of ^1H in small granules of $\text{NbH}_{0.7}$. The importance of particle size is evident in their estimate of the typical $G_0 \approx 3\chi_0 B_0/R$, where χ_0 is the magnetic susceptibility of lithium and R is a typical particle radius. In lithium, for $B_0 = 1.0 \text{ T}$, G_0 exceeds 0.1 T m^{-1} (10 G cm^{-1}) for particle radii of about 10^{-5} m . If the distribution of values of G_0 is symmetric about zero, the effect of the cross term would vanish for $\delta G \gg \tau G_0$. The effect of the cross term in second order is to reduce the *apparent* value of D deduced from the data.⁵⁹ G_0 can be reduced by reducing B_0 or by using larger particles. For metals, small particles are needed for penetration of the rf field and a good coil filling factor. This and a loss of signal-to-noise ratio at lower fields

work against reduction of G_0 . Pulse techniques for reducing or eliminating the cross term are listed in Section 3.3.4

3.3.3 Restricted Diffusion

In the derivations of the echo attenuation, it is assumed that the sample has infinite extent. For the PFG experiment, this means that $(2D\Delta)^{1/2} \ll d$, where d is the spacing between sample boundaries in the direction of the gradient. If this condition is not well met, the apparent value of D will be less than the true value. For some high diffusivity solids such as metal hydrides and fast ion conductors, diffusion might be restricted in the time of PFG measurements. A practical expression for echo attenuation in the PFG experiment on samples with spherical boundaries has been calculated by Murday and Cotts⁵⁹ who adapted the ‘constant gradient’ model of Newman.⁶⁰ Tanner and Stejskal⁶¹ have calculated expressions for PFG echo attenuation for planar, cylindrical and spherical boundaries in the approximation that $\delta \ll \Delta$. Kärger, Pfeifer, and Heink⁶² have reviewed the principles and applications of diffusion measurements by NMR.

3.3.4 Other Pulse Sequences

In the PFG spin echo experiment, the minimum measurable diffusion coefficient is inversely proportional to the diffusion time Δ , and Δ is limited by T_2 of the spin system. In systems where $T_1 \gg T_2$, the stimulated spin echo experiment can provide a greater diffusion time, since the time between the defocusing and refocusing intervals is limited by T_1 . Tanner⁶³ proposed the stimulated echo sequence shown in Figure 10. In this sequence δ is still limited by T_2 , but the diffusion time is limited by T_1 . The cost of gaining an increase in Δ is an intrinsic reduction in the echo amplitude by a factor of $\frac{1}{2}$ created by the ‘storage’ of the spin magnetization along the z axis between second and third rf pulses. Tanner calculated the echo attenuation for the stimulated spin echo PFG experiment to be

$$F[t = (\tau_1 + \tau_2)] = -\gamma^2 D \left\{ \delta^2 \left(\Delta - \frac{1}{3}\delta \right) G^2 + \tau_1^2 \left(\tau_2 - \frac{1}{3}\tau_1 \right) G_0^2 - \delta [\tau_1^2 + \tau_2^2 + \delta(t_1 + t_2) + \frac{2}{3}\delta^2 - 2\tau_1\tau_2] \mathbf{G} \cdot \mathbf{G}_0 \right\} \quad (25)$$

Figure 10 Timing of rf and magnetic field gradient pulses for the PFG stimulated echo experiment. The applied gradient is G , and G_0 is the background gradient. The stimulated echo is shown peaking at $t = (\tau_1 + \tau_2)$. (Reproduced by permission of The American Institute of Physics from J. E. Tanner, *J. Chem. Phys.*, 1970, **52**, 2523)

where $t_2 = \tau' - (t_1 + \delta + \Delta)$. The times in equation (21) are defined in Figure 10. The diffusion time Δ is approximately $(\tau_2 - \tau_1)$.

A number of techniques have been developed to reduce or eliminate effects of the cross term in equations (20 and 21). Karlick and Lowe⁶⁴ invented a very effective pulse sequence that *eliminates* the cross term and substantially reduces the effect of the G_0^2 term relative to the G^2 term. It requires bipolar (or alternating) gradient pulses, and utilizes the Carr–Purcell⁶ spin echo train with one gradient pulse inserted between each pair of π pulses; that is, δ is limited by 2τ instead of τ . In this scheme, the minimum usable Carr–Purcell sequence has five π pulses, and it can be extended by units of four such pulses at a time. The technical requirement of bipolar current pulses is not insignificant.

The Karlick–Lowe concept has been extended to the stimulated echo experiment,⁶⁵ with three different sequences that eliminate the cross term in the expression for echo attenuation. All these sequences use bipolar gradient pulses. One simple unipolar sequence reduces the ratio of the cross term to the G^2 term by a factor of about τ/Δ , which is less than the factor of about unity in the Tanner stimulated echo PFG experiment. In summary, the systematic errors due to background gradients can be nearly eliminated in diffusion coefficient measurements (see *Diffusion Measurements by Magnetic Field Gradient Methods*).

4 APPLICATIONS OF NMR TO DIFFUSION IN SOLIDS

4.1 Solids with Low Vacancy Concentrations

4.1.1 Lithium

Solid lithium is a good example of a simple elemental low-vacancy solid which has been investigated by relaxation rate and PFG diffusion coefficient measurements. Lithium has the b.c.c. structure from about 77 K to its melting point at 454 K. The ^7Li relaxation times have been measured over this full temperature range, covering both the strong and weak collision regimes, and they have been analyzed over eight decades of lithium jump rates from about 3 s^{-1} to $3 \times 10^8\text{ s}^{-1}$ between 200 K and the melting point.⁶⁶ (Messer and Noack⁶⁶ give references to earlier works.) Direct PFG measurements of D in the solid have been made by Mali et al.⁶⁷ at temperatures above about 350 K where $D > 10^{-13}\text{ m}^2\text{ s}^{-1}$ for both ^6Li and ^7Li in nearly isotopically pure and mixed samples. There is consistency between these D measurements and lithium atomic jump rates analyzed from relaxation data using lattice specific encounter models. These results demonstrate the importance of assembling relaxation data over a wide range of NMR frequencies as well as temperature. An exemplary data set⁶⁸ for R_1 and $R_{1\rho}$ is shown in Figure 11.

Messer and Noack⁶⁶ combined the R_1 data of Figure 11 with $R_{1\rho}$ data⁶⁹ at one ω_1 and strong collision data.⁵³ These data were analyzed with the monovacancy encounter theory of Wolf²⁸ and the encounter model with divacancies,⁷⁰ for the self-diffusion coefficient with the following expected temperature dependence:

$$D_{\text{SD}} = D_{10} \exp(-E_1/RT)[1 + D_{12} \exp(-E_{12}/RT)] \quad (26)$$

Figure 11 Temperature dependences of T_1 and $T_{1\rho}$ of ^7Li in solid lithium. The T_1 curves are labeled with the NMR frequency, and the $T_{1\rho}$ curves list the rotating frame magnetic field in oersteds (1 Oe $\equiv 1 \times 10^{-4}$ T). The upper limits on values of relaxation times is set by the conduction electron relaxation mechanism. (From Messer⁶⁸)

D_{SD} simply expresses the mean jump rate τ_d^{-1} of lithium atoms in that, by definition,⁶⁶ $D_{\text{SD}} = l^2/(6\tau_d)$, where l is the nearest neighbor distance in the b.c.c. lattice. Results of the analysis are plotted in Figure 12. The evident deviation from the Arrhenius relationship in equation (22) at high temperatures is attributed to divacancies and is offered as the explanation of the form of the curve in Figure 12. They obtained $E_1 = 50.2\text{ kJ mol}^{-1}$, $E_{12} = 16.7\text{ kJ mol}^{-1}$, $D_1 = 3.8 \times 10^{-6}\text{ m}^2\text{ s}^{-1}$, and $D_{12} = 2.5 \times 10^{-2}\text{ m}^2\text{ s}^{-1}$. Using the set of data in Figure 11 with a modified formula for the strong collision regime, Messer⁶⁸ obtained values of D_{SD} a factor of about 1.5 greater than those he reported previously.⁶⁶ A similar analysis has been done in solid sodium,⁷¹ but without the availability of R_1 data which were masked because of the stronger conduction relaxation rate in sodium.

PFG measurements⁶⁷ of D are given in Figure 13 for three lithium samples having different isotopic composition. These data occur in the high temperature range where the divacancy term in equation (22) appears to be in evidence. The PFG measurements⁶⁷ of D have been compared with the two sets of D_{SD} from Messer and Noack⁶⁶ and Messer.⁶⁸ Theoretically, for the b.c.c. lattice with monovacancies only, $(D/D_{\text{SD}}) = f_t = 0.727$. Mali et al.⁶⁷ found values of this ratio to be between about 0.33 and 0.60, depending on temperature for the data analysis used by Messer and Noack.⁶⁶

4.1.2 Fluorides

As noted in Section 2.2.3, the work^{32–34} on pure and doped BaF_2 represents a very successful application of NMR to a low-vacancy system. The comparison made by Figueroa et al.³⁴ between values of D calculated by analysis of relaxation rate data and values of D deduced from electrical conductivity is shown in Figure 14 (from the review by Chadwick).⁷² Experimentalists who have ever taken NMR data from samples at temperatures within a few hundred degrees of these high temperatures (up to about 1200 K) will especially appreciate Figure 14. The same research group settled many questions regarding the interpretation of relaxation rates in PbF_2 at high

Figure 12 Temperature dependence of the self-diffusion coefficient D_{SD} based on ^7Li relaxation times measured in solid lithium. (+) T_1 from Messer and Noack;⁶⁶ (■) $T_{1\rho}$ from Ailion and Slichter;⁵³ (○) $T_{1\rho}$ from Weithase and Noack;⁶⁹ (●) mass spectroscopy tracer diffusion coefficients; (—) D_{SD} fit to equation 22; (---) Arrhenius fit. temperatures by making direct PFG diffusion measurements of fluoride ions and showing their agreement with D deduced from conductivity measurements.⁷³

4.1.3 Plastic Crystals

Some molecular crystals with approximately spherical molecules, e.g. adamantane, have a plastic phase just below the melting point in which the molecules are in a state of rapid reorientation combined with translational diffusion. Many of these solids have low melting points, and so the transition to the plastic phase limits the temperature range for their study. The rapid reorientation effectively averages out the intramolecular dipole interaction and provides the fluctuating fields needed for spin relaxation. The understanding of the rotational motion has relied on analysis of NMR relaxation rate measurements. Analyses of the several spin relaxation rates have identified translational jumping rates of the rotators in the plastic phase, but the jump rates are usually so low near the melting point that PFG measurements of D have not been practical. Typically, the plastic crystal has f.c.c. or b.c.c. structure, considering the equilibrium sites of the rotators, and

Figure 13 Temperature dependence of ^7Li diffusion coefficients in solid lithium measured with the PFG spin echo technique. (○, ●) Natural lithium (92.6% ^7Li , 7.4% ^6Li); (▲) sample with 99.97% ^7Li ; (×) sample with 95.5% ^6Li , 4.5% ^7Li . (○) Magnetic field $B_0 = 2.11$ T; for all other symbols, $B_0 = 5.17$ T. The data near 400 K are shown enlarged in order better to display the error bars. (Reproduced by permission of IOP Publishing Ltd from M. Mali, J. Roos, M. Sonderegger, D. Brinkmann, and P. Heithjans, *J. Phys. F: Met. Phys.*, 1988, **18**, 403)

monovacancy diffusion obtains in these systems. Observations of R_2 and the peak(s) in $R_{1\rho}$ at one or more values of ω_1 have been most useful in exposing diffusion because τ_d is usually too long to allow observation of the peak in R_1 at the selected NMR operating frequencies. Figure 15 shows relaxation time data for the ordered and the b.c.c. plastic phase

Figure 14 Temperature dependence of ^{19}F diffusion coefficients in BaF_2 single crystals: (a) pure; (b) doped with 0.04 mol% KF ; (c) doped with 0.05 mol% LaF_3 . Diffusion coefficients were calculated from relaxation time measurements using the monovacancy encounter model. (■) From T_1 ; (□) from $T_{1\rho}$; (+) from $T_{1Dipolar}$; (—) calculated from the ionic conductivity. The changes in slope occur between the extrinsic and intrinsic regions.^{34, 72} (Reproduced by permission of the Royal Society of Chemistry from A. V. Chadwick, *J. Chem. Soc. Faraday Trans.*, 1990, **86**, 1157)

Figure 15 Temperature dependences of T_1 and $T_{1\rho}$ for ^1H in hexamethylethane. Region I is the plastic crystal phase, and region II is the ordered phase. The NMR frequency is 14.3 MHz. of hexamethylethane (HME).⁷⁴ The reorientational motion in the low-temperature phase produces the minimum in T_1 and in $T_{1\rho}$, and the effects of the translational motion in the plastic phase is similarly evident. In the plastic phase, second moment measurements indicated isotropic molecular reorientation.

From the encounter model for monovacancies,^{25,28} estimates of D deduced from NMR relaxation times for three compounds have been compared with D obtained from radio-tracer results, with acceptable agreement.⁷⁵ In HME, $D \approx 1 \times 10^{-12} \text{ m}^2 \text{ s}^{-1}$ at the melting point (374 K). Boden has prepared a review of NMR in plastic crystals.⁷⁶

4.2 High-Vacancy Solids

4.2.1 Metal Hydrides

Nearly half of the transition metals, the rare earth metals, and many intermetallic compounds and alloys can absorb large amounts of hydrogen, which for some systems can exceed three hydrogen atoms for each metal (M) atom. Usually the hydrogen resides as atoms in one set of interstitial sites of the metal host lattice, though not necessarily the lattice of the pure, unhydrided metal. Norberg⁷⁷ explored the application of NMR early to metal hydrides by conducting pulsed and continuous wave experiments on PdH_x and identifying motional narrowing, susceptibility shifts, and testing for the conduction electron relaxation mechanism.

High diffusivities of the hydrogen atoms (i.e. those exceeding $10^{-9} \text{ m}^2 \text{ s}^{-1}$) can occur in these metal–hydrogen

(M–H) systems. Wide ranges of hydrogen solubility exist wherein hydrogen atoms reside nearly randomly (subject to site-blocking effects) on one set of sites. Vacancy concentrations can be large. Fractional concentrations exceeding 0.2 are not unusual, but ‘monovacancy’ levels are rare. This means that there are opportunities in M–H systems to use mean field,²⁶ multiple scattering,¹⁸ or Monte Carlo³⁹ models in relaxation rate analyses. Because of its low atomic number, hydrogen has a weak conduction electron relaxation mechanism⁷⁸ to compete with relaxation due to diffusion. T_1 and T_2 are sufficiently long to allow use of the PFG methods for measuring D .

Most M–H systems are good metals. As noted earlier, systematic errors in PFG measurements are reduced if metal particles are made as large as possible. This consideration favors lower laboratory frame NMR frequencies, so that 7 MHz was selected⁴⁰ for the determination of the step length of hydrogen in the subhydrides of TiH_x . In the first PFG measurement⁷⁹ of D for hydrogen in the metal hydride, $\text{NbH}_{0.6}$, a cylindrical single crystal was used partly to avoid the concerns over small particles. This experiment⁷⁹ also combined R_1 and D measurements to determine the step length. In a series of measurements on b.c.c. hydrides, summarized by Sevilla and Cotts,⁸⁰ two special PFG sequences^{64,81} were used to eliminate the $\mathbf{G} \cdot \mathbf{G}_0$ cross term. Hydrogen is found to be more mobile in the b.c.c. host metals than in those with more closely packed metal atoms.⁸⁰

The combining of measurements of D and R_1 to learn about step lengths has been done impressively by a collaboration between the Stuttgart Max Planck Institute and Iowa State University groups. Majer et al.^{42,82} have measured D for ^1H using the PFG stimulated echo⁶³ for five concentrations of hydrogen in the subhydride ZrH_x at temperatures from 600 to 950 K using applied gradients up to 25 T m^{-1} . Their results are shown in Figure 16. Using lattice specific R_1 theories,^{14,18,43} combined with R_1 measurements by Han et al.⁸³ on the same samples, it was demonstrated that hydrogen atoms jump between nearest neighbor tetrahedral interstitial sites.

Figure 16 Temperature dependences of diffusion coefficient of hydrogen in five samples of ZrH_x measured by the ^1H PFG stimulated echo. (—) Fits to the data with the Arrhenius equation. (Reproduced by permission of IOP Publishing, Ltd from G. Majer, W. Renz, and R. G. Barnes, *J. Phys. Condens. Matter*, 1994, **6**, 2935)

Non-Arrhenius plots at high temperatures for high concentration samples have been attributed to having a small fraction of hydrogen atoms located on a second, but as yet unidentified, site. References cited by Han et al.⁸³ offer a good introduction to the literature on applications of NMR in metal hydrides (see *Hydrogen–Metal Systems*).

4.2.2 Fast Ion Conductors

In the more than 20 years that there has been a high level of interest in understanding ionic conductivity in solids, NMR has been an important tool for the study of structure and ionic motion in what are regularly known as ‘solid electrolytes’ or ‘superionic conductors’. The work on the fluorides which has already been mentioned^{32–34,74,75} is representative of the application of NMR in this field. The search for high ionic conductivity has identified a wide variety of solids that meet the necessary criterion. These include crystals, glasses and polymer electrolytes. The recent report by Brinkmann⁸⁴ provides an informative and comprehensive review of NMR in this field.

Interesting examples of combining R_1 measurements with the PFG technique for D are found in the work by the University of Zürich group on ^{109}Ag ($I = \frac{1}{2}$) in fast ion conductors. Because nuclear moments of both silver isotopes are less than one-twentieth of that of ^1H , it is necessary to have access to high magnetic fields to get the NMR frequency into a workable range (above 10 MHz). However, even in this frequency range signals will be low because of the low magnetogyric ratio of ^{109}Ag . Compared to working with large γ spins such as those of ^1H , ^7Li , ^{19}F , or ^{23}Na , doing the PFG experiment on silver at first appears daunting because of the γ dependence of the important exponent in the echo attenuation expression in equation (20): $[\gamma^2 D \delta^2 (\Delta - \frac{1}{3} \delta) G^2]$. This term should equal or exceed unity in order effectively to attenuate the echo. However, because γ of ^{109}Ag is small, its relaxation rates are also reduced, so the difference can be made up by increasing the times δ and Δ in the sequence. Nevertheless, the long relaxation times and the lower NMR signal amplitudes mean longer signal accumulation times for an acceptable signal-to-noise ratio and good data.

Looser et al.⁸⁵ used the PFG spin echo technique to measure D in the two isostructural crystals RbAg_4I_5 and KAg_4I_5 from 150 to 300 K covering the α and β phases of these crystals. They found little difference in D between these crystals except in the α – β phase transition temperatures, which are visible in Figure 17. From comparison between D measured by the PFG and D_σ deduced from conductivity data, they concluded that there was increased correlation of the silver motion in the β phase.

In their work on β - Ag_3SBr , Huber et al.⁸⁶ brought together experimental data on the temperature, pressure, and NMR frequency dependence of the silver R_1 and PFG D measurements. Having the diffusion data allowed them to identify a model for silver motion that includes local hopping between the four silver sites within one face of the cubic unit cell and diffusional jumps between neighboring faces.

5 FURTHER READING

Review papers provide special perspectives on their selected applications of NMR and references to other works of interest.

Figure 17 Temperature dependences of diffusion coefficients of silver in fast ion conductors, RbAg_4I_5 and KAg_4I_5 . ^{109}Ag PFG spin echo measurements: (●) RbAg_4I_5 ; (×) KAg_4I_5 ; (○) radioactive tracer data. 1 INTRODUCTION

1.1 Properties of Fluorine-19

Aside from carbon and hydrogen, fluorine-19 is possibly the most-studied nucleus. The reasons for this include both the properties of the nucleus and the practical importance of molecules containing this element. The nucleus ^{19}F has the advantage of 100% natural abundance and a high magnetogyric ratio, about 0.94 times that of ^1H . The chemical shift range is 20 or more times that of hydrogen, so that resonances of different fluorine nuclei are usually well separated. Furthermore, spectral positions are sensitive to the environments of fluorine atoms. The nuclear spin quantum number is $\frac{1}{2}$, and thus relaxation times are sufficiently long that spin–spin splittings may be resolved. Long-range spin–spin coupling constants have substantial magnitude; this has the advantage of providing extensive connectivity information but, for highly fluorinated molecules, it tends to create large spin systems and make resonances very complex and non-first-order.

Fluorinated molecules have achieved industrial prominence in the production of polymers, as surface active and lubricating materials, as refrigerants, and as anesthetics and drugs. Fluorine is particularly useful as a tracer in biological systems, as there is essentially no natural background, and it is often possible to substitute a single fluorine atom for a hydrogen atom without materially changing the properties of a molecule such as a protein.

Observation of ^{19}F in high-field spectrometers may present some problems, and care is required in selecting appropriate instrumentation. At a field of 11.75 T, corresponding to 500 MHz frequency for protons, the full spectral range for ^{19}F approaches 0.5 MHz. This requires appropriate high speeds for the analog-to-digital converter and wide bandwidths for the amplifiers, as well as large data arrays to afford good spectral resolution for narrow lines. Furthermore, uniform excitation over the whole spectrum requires quite short pulses from the transmitter.

1.2 Reviews and Compilations of Data

A small paperback volume by E. F. Mooney presents an introduction to ^{19}F NMR spectroscopy.¹ It includes a variety of typical spectra, as well as some representative NMR parameters for organic molecules, and it gives the reader an excellent feel for the field. Two full volumes have been devoted to compilations of chemical shifts,^{2,3} one is devoted almost entirely to discussions and tables of spin–spin coupling constants,⁴ and a database for C_xF_y compounds has been described.⁵ A number of reviews covering publications on ^{19}F NMR over specific periods of 1 or 2 years have been included in the *Annual Reports on NMR Spectroscopy*.^{6–12}

2 CHEMICAL SHIFTS

The shielding of fluorine nuclei varies quite widely, as illustrated in Table 1 for the range from XeF_6 at low fields to CH_3F at high fields. Several specific structure types will be discussed later. Compared with the situation for hydrogen, the effects of anisotropic magnetic fields, such as those generated by ring currents, are relatively much less important for fluorine, and the nature of the bonding of the atom has a much greater influence. The presence of unshared electron pairs leads to the existence of excited molecular states at relatively low energies, and these are mixed into the ground state as the result of a perturbation by the magnetic field of a spectrometer, producing an unshielding or ‘paramagnetic’ effect.

Table 1 Representative ^{19}F Chemical Shifts (in ppm to High Frequency of CFCl_3)

XeF_6	550	CFBr_3	7
F_2	430	CF_2Cl_2	–8
ReF_7	345	CF_3CH_3	–62
$\text{ClF}_{5,\text{eq.}}$	412	SiF_6^{2-}	–127
$\text{ClF}_{5,\text{ax.}}$	247	BF_3	–131
WF_6	166	$\text{CF}_2=\text{CF}_2$	–135
$\text{C}_6\text{H}_5\text{SO}_2\text{F}$	66	CH_3F	–272

2.1 References for Chemical Shift Measurements

Many early reports of ^{19}F shifts were based on the use of trifluoroacetic acid as an external reference. Because this is a hazardous and reactive material and because values based upon any external reference suffer from errors related to the magnetic susceptibility and geometry of the sample, it has been replaced by the internal reference fluorotrichloromethane, assigned a shift of zero. Under poor spectrometer resolution, the spectrum of this material has only a single peak, but in an instrument with good resolution this is resolved into four lines, corresponding in order, from low frequency to high frequency, to the presence of three, two, one, or no ^{37}Cl nuclei in the molecule. Thus a different result is obtained if the position of one of the individual lines is taken as reference rather than the center of gravity of the overall pattern. However, effects of medium and temperature on shifts are so large for fluorine that they are likely to lead to greater uncertainties than does the small isotope effect in the reference material.

Table 2 Chemical Shifts of Reference Compounds (in ppm to High Frequency of CFCl_3)

CFCl_3	0
$\text{CFCl}_2\text{CF}_2\text{Cl}$	-68.05
$\text{CFCl}_2\text{CF}_2\text{Cl}$	-72.2
$\text{CF}_3\text{CO}_2\text{H}$	-76.6
C_4F_8	-135.2
C_6F_6	-163

Since the resonance of CFCl_3 is well removed from those of most fluoroorganic molecules, and since many of these molecules require $\text{CF}_2\text{ClCFCl}_2$ in order to dissolve, it is often convenient to use one of the multiplets of this material as a reference for the sample peaks. The shift values for these two resonances compared with CFCl_3 , along with the shifts of a few other materials which have sometimes been used as references, are given in Table 2.

By general agreement, the direction of the chemical shift is taken as positive in the direction of higher *resonance frequency* or lower magnetic field. This requires that the great majority of shift values for ^{19}F be negative with respect to CFCl_3 . It is appropriate in discussing factors affecting *nuclear shielding* to follow the opposite convention: the greater the degree of shielding, the further to high field or *lower frequency* is the resonance.

2.2 Shifts of Fluorines Attached to Carbon

Some generalizations may be made about the ranges of shifts to be found in various environments in highly fluorinated organic molecules. First, we consider the effects of halogens or oxygen, along with other fluorine atoms in aliphatic molecules. In specifying the group in which the fluorine is found, the letter X will be used to represent either another fluorine atom, or an atom of chlorine, bromine, or oxygen. Thus $-\text{CFX}_2$ might be $-\text{CF}_3$, $-\text{CF}_2\text{Br}$, $-\text{CFCl}_2$, $-\text{CF}_2\text{O}-$, and so on, and $-\text{CFX}-$ might be $-\text{CFCl}-$ or $-\text{CFBr}-$.

The fluorine resonance in CF_3 in a saturated molecule appears at -75 to -82 ppm with respect to CFCl_3 and in other $-\text{CFX}_2$ units at -65 to -80 ppm. If the shift in $-\text{CF}_2\text{Cl}$ is compared with that in $-\text{CF}_3$, it is found that this chlorine substitution produces a high-frequency (*downfield*) shift or unshielding of about 10 ppm. However, the second substitution of a chlorine for a fluorine atom, giving $-\text{CFCl}_2$, has the opposite effect, so that the resonance is now more shielded than, and about 5 ppm upfield from, that of $-\text{CF}_2\text{Cl}$. The shifts of CF_3 attached to oxygen or to an alkenic carbon are in the region of -50 to -60 ppm.

The shifts of the fluorine in a $-\text{CFX}$ group in a saturated molecule are observed at about -120 to -130 ppm, and here, in contrast to the $-\text{CFX}_2$ case, substitution of one fluorine by a chlorine, forming a CFCl group, causes an increased shielding of about 6-8 ppm. In a straight-chain fluorocarbon unit, the CF_2 group next to the terminating CF_3 can be identified because it is at -127 ppm, rather than at the -122 ppm characteristic of CF_2 fluorines flanked by other CF_2 groups.

The effect on nearby fluorine atoms of substitution of a chlorine for a fluorine atom in a highly fluorinated straight chain is an unshielding of about 6 ppm if the chlorine is on the adjoining carbon, and about 3 ppm if the chlorine is on a

carbon atom one removed from the fluorine being observed. Calculations have been made to predict and correlate shifts in a wide variety of highly halogenated molecules.^{13,14}

Shifts to lower field or to higher frequency, as for chlorine substitution, are produced by substitution of bromine on a vicinal carbon. The effect of chlorine or bromine has been attributed to a van der Waals interaction between the halogen and fluorine and termed 'repulsive unshielding'. Similar unshielding is caused by crowding of a fluorine atom by a methyl group.¹⁵

Substitution of hydrogen for fluorine in either $-\text{CF}_2$ or $-\text{CF}_2\text{X}$ increases the shielding of the remaining fluorine. A tertiary fluorine atom is usually found at a relatively high field (about -160 to -180 ppm).

A carbonyl group in a perfluorinated chain typically causes unshielding of 2-5 ppm for fluorine atoms attached to the α carbon atoms, and an amine nitrogen in the chain produces an unshielding effect for α fluorine atoms of 5-10 ppm. A fluorine atom attached directly to a carbonyl carbon, in an acid fluoride unit, resonates at +30 to +50 ppm.

Fluorine atoms attached to an alkenic carbon atom appear anywhere in the range -50 to -220 ppm. In aromatic molecules, a fluorine substituent resonates anywhere from -100 to -180 ppm. The chemical shift difference produced by a second substituent in the *meta* or *para* position on a benzene ring correlates well with Hammett substituent parameters. If the substituent is *ortho* to the fluorine atom, substantial deviations appear, caused either by van der Waals forces or by electric field effects, and are experienced at the relatively short distances between the fluorine and the *ortho* substituent.

2.3 Shifts of Fluorine Atoms Attached to Other Nonmetals

Many fluorine atoms attached to nitrogen, oxygen, or sulfur resonate to low field or high frequency of CFCl_3 and thus are assigned positive shift values. In $\text{F}-\text{O}-\text{C}$ units, the shift is often in the range 144-155 ppm,¹⁶ but may vary as much as ± 100 ppm from this region. In an NF_2 group, the shift is 15-20 ppm if the group is attached to CF_2 , 20-30 ppm if attached to saturated $-\text{CF}-$, 50-60 ppm if attached to CH_2 in an aliphatic chain, and 30-45 ppm if attached to CH in an aliphatic chain. In an $-\text{NF}-$ group the shifts are -80 to -120. In $=\text{NF}$, there is a very wide variation with the attached structure, from +55 to -67 ppm.¹⁷

Several compounds illustrate these shifts as well as shifts of fluorine attached to sulfur. In $\text{SF}_5\text{SO}_3\text{F}$, the fluorine atom attached to oxygen is at 46 ppm, the equatorial and axial fluorine atoms on sulfur are at 73 and 57 ppm, respectively. In FSO_3F , the OF is at 249 ppm and the SF is at 37 ppm.¹⁸ In OF_2 , the shift is 250 ppm, also far downfield. In SF_5NF_2 , the NF_2 fluorine atoms are at 78 ppm, the equatorial fluorine atoms on sulfur are at 38 ppm, and the axial fluorine atom is at 50 ppm; with nitrogen attached to the sulfur, the equatorial-axial order is reversed from that when the octahedral sulfur atom is attached to another sulfur or to oxygen.

2.4 Isotope Effects on Shifts

Because fluorine is relatively sensitive to its environment, it exhibits considerable changes in chemical shift when

a nearby atom is replaced by an isotope. As mentioned above, the differential effect of ^{35}Cl versus ^{37}Cl attached to the carbon bearing the ^{19}F is readily resolved, and three-bond effects are also measurable. Studies of isotope shifts in several molecules show that they increase substantially with decreasing temperature, a behavior consistent with an explanation relating them to populations of vibrational energy levels.¹⁹

Replacement of ^{12}C by ^{13}C , either for the atom to which the fluorine is attached or for the carbon one removed, gives a quite measurable shift, usually to lower frequency. A consequence of the isotope effect is that ^{13}C satellites in a fluorine spectrum are not symmetrical about the ^{12}C –F resonance. Table 3 lists some carbon isotope effects on fluorine.

Table 3 Shifts of ^{19}F Resonance (in Hz to Lower Frequency in a Spectrometer at 94.1 MHz) on Substitution of ^{13}C for ^{12}C

Molecule	One-bond shift (Hz)	Two-bond shift (Hz)
$\text{CF}_2=\text{CCl}_2$	9.20	2.50

1,1,2,2-Tetrafluoro-3,3-dichlorocyclopropane	10.74	

Isotope shifts also result from the replacement of a nearby hydrogen atom by deuterium or by tritium.^{20,21} Increased shielding of the fluorine in fluorobenzene is produced by substitution of ^2H at any ring position or by substitution for the three hydrogen atoms in a *para*-methyl group. If one is dealing with a nonrigid molecule, there is always the possibility that a change in chemical shift may arise in part from the effect of the isotope on a conformational equilibrium, as well as on an ‘intrinsic’ property of a specific geometrical structure. This seems to be the situation for trifluoromethylcyclohexane and may also be true for vicinal deuteration in monofluorocyclohexane.²²

3 INDIRECT SPIN–SPIN COUPLING

Spin–spin coupling, usually represented by the symbol J , is an interaction transmitted from one nucleus which has a spin, through the electron cloud in a molecule, and then from the electrons to a second nucleus. The magnitude and sign of J is often characteristic of structural or geometrical relationships between the two nuclei involved, as well as of the nature of bonding of the nuclei. A number of attempts have been made to develop Karplus-type relationships for the angular dependence of coupling of ^{19}F to other nuclei, particularly ^1H or ^{13}C , but the difficulty of treating the effects of substituents, including that of fluorine itself, has led to only modest success for these relationships.

The value of J may be used as a test for the conformation of a fluorinated molecule which may exist in two structures. If the conformations are equilibrating rapidly, the observed J is a

weighted average of the values in the two forms. The question then arises whether a change in conditions of temperature or solvent that affects the conformational equilibrium might also affect the values of J in the individual conformers. Experience indicates that the intrinsic values of J for interactions involving fluorine are more sensitive to conditions than are those for hydrogen, which are almost independent of circumstances.

In fluoropropenes, in which one would not expect conformational changes to occur, the J values in the vinyl moiety change by 1–2 Hz with a temperature change of 150 °C and by a few tenths of a hertz with a change in medium. In $\text{CF}_2=\text{CFCF}=\text{O}$, for which the two-bond constants are 4.0 and <1 Hz in the two conformational isomers frozen out at low temperature, the value at room temperature is 6.0 Hz, well outside the possible range for a weighted average.²³ Solvent and temperature effects have been shown to be appreciable for several types of coupling constant in fluorobenzene and 1,2-difluorobenzene.²⁴

3.1 Trends in Homonuclear Coupling Constants

Coupling constants between fluorine atoms are usually relatively large compared with the homonuclear couplings of hydrogen atoms, and they extend over much longer distances than do those of hydrogen. Some ranges of values are given in Table 4, and J values for several perfluorinated molecules are shown in Figure 1.

Three-bond F–F couplings in substituted ethanes have been found to depend upon the sum of the electronegativities of the other four atoms or groups attached to the two carbon atoms. The higher the sum of the electronegativities, the smaller the magnitude, until for the highest possible value of the sum, corresponding to four fluorine atoms in hexafluoroethane, the value of J has gone through zero and changed sign. Calculations indicate that this behavior is the result of offsetting contributions of opposite sign from various pathways for transmission of spin information. The value of $^3J(\text{F},\text{F})$ for hexafluoroethane may be measured by observing the carbon-13 satellites for those molecules containing one carbon-13 atom, in which the fluorine atoms attached to that carbon atom are no longer equivalent to those attached to ^{12}C .

In the trifluorovinyl group, the values of $^3J_{\text{trans}}$ are surprisingly invariant, ranging only from about 106 to 130 Hz for a wide range of substituents. The values of $^3J_{\text{cis}}$, in

Table 4 Typical Values of Homonuclear Fluorine–Fluorine Coupling Constants

Structure	J (Hz)
Two-bond, F–C–F, aliphatic, noncyclic	170–220
Two-bond, three-carbon ring	150–180
Two-bond, four-carbon ring	190–230
Two-bond, epoxide ring	13–44
Two-bond, oxetane ring, on carbon next to oxygen	84–95
Two-bond, F–C–F, trifluorovinyl	5–100
Three-bond, F–C–C–F, aliphatic	0–30
Three-bond, alkene, <i>trans</i>	–106 to –127
Three-bond, alkene, <i>cis</i>	–24 to –65
Three-bond, aromatic	18–35
Four-bond, aromatic	0–15
Five-bond, aromatic	4–16

Figure 1 Homonuclear ^{19}F – ^{19}F spin–spin coupling constants in three typical unsaturated fluorocarbon molecules. Values of J are given in hertz, adjoining the lines which link the two interacting nuclear types

contrast, vary from 24 to 65 Hz. The largest values are those where a halogen or an oxygen atom is bonded directly to the vinyl group, suggesting that it is the availability of lone-pair electrons that is significant.²⁵

In contrast with proton–proton coupling across an ether oxygen atom, which is usually unresolvable, fluorine–fluorine coupling may be easily observed in a similar situation. Table 5 includes some values for $J(\text{F},\text{F})$ in several simple ethers containing fluorine.

Table 5 Coupling Constants in Fluoroethers

Compound	$^4J(\text{F},\text{F})$ (Hz)	$^2J(\text{F},\text{H})$ (Hz)
CF_3OCF_3	8.2	
$\text{CF}_3\text{OCF}_2\text{CF}_3$	8.5	
CF_3OCHF_2	4.0	69
$\text{CHF}_2\text{OCHFCl}$	5	58, 70
$\text{CHF}_2\text{OCFCl}_2$	4	69
$\text{CHFClOCF}_2\text{Cl}$	4.5	59
$\text{CF}_3\text{OCFCICHCl}_2$	11	

3.2 Heteronuclear Coupling

3.2.1 Coupling to Hydrogen

Two-bond couplings through carbon are typically 40–60 Hz and are very characteristic in both ^{19}F and ^1H spectra for $-\text{CF}_2\text{H}$, $-\text{CFH}_2$, or $-\text{CFH}$ –groups. Table 5 illustrates the larger values, up to 80 Hz, found when the carbon is attached to an ether oxygen atom. Three-, four-, or five-bond coupling constants in aromatic compounds are about the same as the analogous H–H coupling constants. Three-bond (vicinal) couplings in aliphatic compounds range from very small values up to 15 Hz.

3.2.2 Coupling to Carbon-13

Multiplets produced by ^{19}F coupling in the ^{13}C spectrum of an organic molecule also containing many hydrogen atoms are easily resolved with the aid of proton broadband decoupling.

Values of $^1J(\text{F},\text{C})$ vary from 160 to 400 Hz in magnitude and are negative in sign, an exception to the general rule that one-bond couplings are positive. On comparison of the values in halo-substituted methanes with that in CF_4 , it can be seen from Table 6 that substitution of other halogens for fluorine increases the value of the coupling constant substantially,

Table 6 Values (in Hz) of $^1J(^{19}\text{F}, ^{13}\text{C})$ in Fluoromethanes

		CF_4	–259		
CHF_3	–274	CF_3Cl	–301	CF_3Br	–323
CH_2F_2	–235	CF_2Cl_2	–325	CF_2Br_2	–352
CH_3F	–158	CFCl_3	–337	CFBr_3	–372

whereas substitution of a hydrogen, except for the first one, reduces the value.

In alkenes, the values of $^1J(\text{F},\text{C})$ are about –300 Hz (our work); in the $=\text{CF}_2$ unit of an alkene which is unsymmetrically substituted, the values of the two coupling constants differ from one another. When a fluorine atom is attached to a carbonyl carbon, the value increases to about –370 Hz. In fluorinated aromatics, values lie between –260 for C_6F_6 and –245 for $\text{C}_6\text{H}_5\text{F}$ when there is no other substituent; electron-withdrawing substituents on the ring increase J , while electron-releasing substituents decrease J . It is tempting to say that the former increase the π -electron donation of the fluorine atom to the ring system, whereas the electron-releasing substituents compete with the tendency for this donation.

The sign of $^2J(\text{F},\text{C})$ is positive, and values are typically 20–45 Hz. The value is about 20 Hz for a single fluorine atom in an aliphatic compound. The magnitude increases with substitution of electronegative groups. The value in alkenes depends upon the substitution pattern and is especially large when an electronegative substituent is *trans* to the fluorine. In benzenoid aromatics, the value is 15–25 Hz, except when the carbon bears a substituent, which is thus *ortho* to the fluorine. In cyclopropane rings, the values are small, between 5 and 15 Hz. An especially large value has been found for the two-bond coupling in the molecule $\text{CFBr}=\text{CFBr}$. Similarly, J between the fluorine attached to the carbonyl and the α carbon atom in (4) is 91 Hz, although 2J between the carbonyl carbon and the α fluorine atom in (4) is only 31 Hz. Some other related molecules with very large values of 2J are listed in Table 7.

Table 7 Molecules with Large Values of $^2J(^{19}\text{F}, ^{13}\text{C})$

Compound	2J between α -C and CFO (Hz)	1J in CFO group (Hz)
$\text{CF}_3\text{CF}_2\text{CF}_2\text{CF}=\text{O}$	78	374
$(\text{CF}_3)_2\text{CFCF}=\text{O}$	66	369
$\text{CF}_2\text{ICF}_2\text{OCF}_2\text{CF}=\text{O}$	93	374
$\text{O}=\text{CFCF}_2\text{OCF}_2\text{CF}=\text{O}$	94	372
$(\text{CF}_3)_2\text{C}=\text{CCICF}=\text{O}$	85	355
$\text{CF}_3\text{CIC}=\text{CCICF}=\text{O}$	84	352

3.2.3 Coupling to Phosphorus and Nitrogen

The one-bond coupling constant to ^{31}P is negative and large. For units such as five-coordinate PF_4 – or XYPF_3 or six-coordinate CH_3PF_5 –, values range from about 700 to 1100 Hz.

Often the fluorine nuclei undergo a pseudorotation process which averages out values for the axial and equatorial positions, but if this process is sufficiently slow, a distinction can be made between the coupling constants for the two fluorine positions and the axial value is smaller, for some molecules by as much as 100–150 Hz, than the equatorial value. In five-coordinate compounds in which one ligand is a CF_3 group, $^2J(\text{P},\text{F})$ is 24–88 Hz for the axial position and 107–190 Hz for the equatorial position, providing stereochemical information about the complexes. The barrier to fluxional behavior in a number of complexes has been obtained from analysis of the NMR lineshapes.

The values for one-bond coupling to ^{15}N are usually between 110 and 160 Hz. In *cis*- N_2F_2 , J is 203 Hz, in *trans*- N_2F_2 it is 190 Hz, but in the azide N_3F it is only 58 Hz.²⁶ There is an unusually large value of 53 Hz for $^2J(\text{F},\text{N})$ in 2-fluoropyridine, perhaps attributable to transmission via unshared electrons. No large couplings are found for adjacent substituents in benzene: in 2-fluoronitrobenzene, $^3J(\text{F},\text{N})$ is 2.66 Hz; and in 2-fluoroaniline, it is about 0.5 Hz. In 2- CF_3 -aniline, $^4J(\text{F},\text{N})$ is 1.68 Hz. In 5-fluorouracil, the two values of 3J are 1.12 and 1.66 Hz.

3.2.4 Coupling to Metals

Fluorine forms bonds to a wide variety of metals. In several binary compounds with nuclei having spin $\frac{1}{2}$ or small quadrupole moments, splittings can be resolved and values of J can be measured. Examples are TiF_6^{2-} , $J = 34$ Hz, and NbF_6^- , $J = 335$ Hz. Mercury compounds show positive two-bond couplings with magnitudes up to more than 2000 Hz and three-bond couplings as large as several hundred hertz. Some other examples are given in Table 8.

In TeF_6 , $^1J(^{125}\text{Te}, ^{19}\text{F})$ is 3746 Hz and in TeF_7^- it is 2876 Hz.²⁷ The smaller value in the latter has been attributed to weaker, more polar bonds. That there is only a single value of J and only a single shift for all six fluorine atoms indicates rapid exchange between axial and equatorial positions. It is interesting that the number of naturally occurring isotopes of tellurium leads to multiple, slightly shifted, fluorine resonances.

3.3 Long-Range Coupling

It has been proposed that many of the examples of coupling between two fluorine nuclei which are separated by a number of bonds (four, five, six or more) may result from overlap of electronic orbitals occupied by electrons which are unshared and therefore not involved in normal covalent

bonding. The term applied to this effect, ‘through space’, is somewhat misleading, since only the anisotropic dipole–dipole interaction is effective through ‘empty’ space. All isotropic coupling is transmitted in some way by electrons, either in bonds or in unshared pairs.

The idea of transmission of the indirect coupling through electrons not involved in bonds was proposed by Petrakis and Sederholm.²⁸ It has since been extended to systems involving nuclei other than fluorine.

Coupling via nonbonding electrons may be invoked to explain the temperature dependence of $^4J(\text{F},\text{F})$ in $\text{CF}_2\text{ClCFClCFCl}_2$ (**5**). As the temperature is lowered from room temperature to -100°C , the value of the coupling between the fluorine atom in CFCl_2 and one of the fluorine atoms in the CF_2Cl unit increases from 17 to 28 Hz, whereas the other 4J decreases from about 13 to 12 Hz. The large coupling at low temperature can be assigned to two fluorine atoms forced to be closer together by the increasing effects of steric repulsions with decreasing temperature, as represented in the diagram for (**5**).

Another example which can be explained by the ‘through-space’ mechanism involves coupling of the fluorine atoms in an oxetane ring with the *ortho* fluorine atoms in a pentaphenyl group substituted in the ring. The molecule (**6**) exists in two isomeric forms, differing in whether the pentafluorophenyl group and the chlorine atom are on the same side or on opposite sides of the ring. In one isomer, $J(\text{F}_A, \text{F}_D)$ is 1.3, $J(\text{F}_B, \text{F}_D)$ is 10.7, and $J(\text{F}_C, \text{F}_D)$ is 11.4 Hz. In the other isomer, $J(\text{F}_A, \text{F}_D)$ is 7.5, $J(\text{F}_B, \text{F}_D)$ is 1.4, and $J(\text{F}_C, \text{F}_D)$ is 0.9 Hz.

There are other examples of long-range coupling which cannot be explained by direct orbital overlap, but are probably associated with electron delocalization in π orbitals. Thus the stereochemistry of fluorinated alkenes and dienes is related to $^3J(\text{F},\text{C})$ in a way not fully explained by nuclear proximity.²⁹

Outstanding among the interactions transmitted by π orbitals are those across aromatic ring systems. A number of these have been related to studies of molecular conformation. In 3,5-dichlorobenzyl fluoride, as an example, $^6J(\text{F},\text{H})$ is related to the rotational orientation of the $-\text{CH}_2\text{F}$ group with respect to the ring.³⁰ Long-range C–F coupling in derivatives of benzoic acid and benzoyl fluoride are related experimentally and theoretically to the dihedral twist angles of the substituent-to-ring C–C bond.³¹ A study of fluorinated methyl phenyl sulfoxides showed that $^5J(\text{F},\text{H})$, $^4J(\text{F},\text{C})$, $^5J(\text{F},\text{C})$, and $^6J(\text{F},\text{C})$ are dependent upon the conformation about the sulfur atom.³²

Table 8 Fluorine–Metal Coupling Constants

Species	Solvent	Coupling Constant (magnitude) (Hz)
VOF_3	THF	110
VOF_4^-	CH_3CN	86
$\text{VO}(\text{CF}_3\text{CO})_3\text{F}^-$	CH_3CN	80
VO_2ClF^-	CH_3CN	207
VO_2F_2^-	CH_3CN	272
NbOF_4^-	CH_3CN	410
$(\text{CF}_3)_2\text{Hg}$	CH_2Cl_2	1263

4 RELAXATION; NUCLEAR OVERHAUSER EFFECTS

Fluorine-19 nuclei may undergo spin-lattice relaxation by the direct dipolar mechanism, in much the same way as do protons. However, because of the presence of unshared electrons, spin-rotation (SR) and chemical shift anisotropy (CSA) mechanisms also contribute to the relaxation of ^{19}F . Because of the additional relaxation pathways, T_1 values are often substantially smaller than for protons in a similar environment.

Early workers reported that the CSA contribution is negligible and that spin rotation predominates. This is true for molecules such as CF_4 or SF_6 , which are small and freely rotating, and for measurements at 2.4 T or lower magnetic field strength. Since the spin-rotation relaxation time decreases with increasing temperature, whereas the dipole-dipole relaxation time increases with increasing temperature, a maximum may be observed for T_1 as a function of temperature, as has been found, for example, for *o*-fluoroiodobenzene at about 110 °C.

Spin-rotation interaction constants can be calculated from the paramagnetic term of the NMR shielding constant.³³ They can also be measured by molecular beam methods, and the values for HF, F_2 , SiF_5 , CF_4 , and CHF_3 show good agreement by the two methods. It should also be possible to calculate the spin-rotation constants from measured spin-lattice relaxation times, but this requires knowledge of the correlation time, and reasonable guesses for the latter give values of the constant too large by a factor of 2 to 3.

Rapid spin-spin relaxation is associated with broadening of spectral lines, such as is caused by inhibition of motion, as occurs with macromolecules. The extent of broadening is related to the anisotropy of the chemical shift, which is often large for ^{19}F . Since the CSA contribution increases with field, the broadening is greater at higher fields, often offsetting the improvement in sensitivity and resolution expected, such as by going to a frequency of 470 MHz. Since macromolecules do rotate more slowly, the SR contribution for the ^{19}F relaxation in them is small, except possibly for freely rotating CF_3 groups.

The nuclear Overhauser effect (NOE) of fluorine nuclei is much like that of protons. Most applications of the NOE to fluorine have been heteronuclear, where the close approach of one or more particular hydrogens atoms to a fluorine atom is monitored. In macromolecules, dipolar interactions are often the predominant T_1 relaxation mechanism, and saturation of protons should fully invert the normal ^{19}F intensities. Under circumstances where the T_1 of the ^{19}F nucleus is shorter than that of the ^1H , it is preferable in a one-dimensional NOE experiment to use the ^{19}F as the source of the Overhauser transfer so that irradiation maintains the nonequilibrium population.

Indirect Overhauser enhancements through ^{19}F from ^1H to ^1H or from ^1H to ^{13}C have been obtained for several cyclic compounds.³⁴ In NOE difference spectra, antiphase doublets were observed for protons undergoing simultaneous scalar coupling and dipolar relaxation with ^{19}F . The geometrical factors inherent in the three-spin NOE were utilized in conformational analysis. NOE measurements have also been used to confirm the proximity of hydrogen nuclei to fluorine

nuclei in some tetrahydroindazole derivatives where long-range coupling between these nuclei was suspected of being the result of a 'through-space' interaction.³⁵

It is interesting that pioneering work in the analysis of the NOE was the application by Solomon and Bloembergen³⁶ to the HF system. Because of the very large value of $^1J(\text{F,H})$ in this molecule (more than 600 Hz), there is relaxation by interrupted scalar coupling, which produces a negative enhancement instead of the positive intensity change expected for the dipole-dipole mechanism.

5 APPLICATIONS TO BIOCHEMICAL PROBLEMS

By virtue of the circumstances that there is almost never any fluorine background in living systems and that fluorine shifts are quite sensitive to the environment, applications of ^{19}F NMR to biochemical problems have been extensive. Several reviews have appeared.^{37,38}

Fluorine NMR has been applied in the investigations of several types of system, perhaps most extensively to proteins. Pioneer work in this field was that of Sykes and Hull,³⁹ who applied ^{19}F relaxation measurements to the study of motions of groups in proteins. Alkaline phosphatase was labeled with fluorotyrosine residues. Both overall rotation of the protein and internal rotation of the aromatic ring contribute to ^{19}F relaxation, which includes a substantial CSA component. Two of the tyrosine rings relax by chemical exchange, indicating that they are free to rotate, and one of the tyrosines relaxes faster in $^1\text{H}_2\text{O}$ than in $^2\text{H}_2\text{O}$, indicating that it is exposed to the solvent.

In other systems, the nature of binding of small molecules to proteins has been studied. On binding of an inhibitor such as cytidine monophosphate (CMP) to ribonuclease S trifluoroacetylated at lysines-1 and -7, the fluorine resonance assigned to lysine-7 splits and becomes pH dependent.⁴⁰ This change could, of course, come either directly from contact of the inhibitor with the lysine or indirectly as a result of a conformational change of the protein caused by the inhibitor. A summary of the considerations involved in using fluorine as a tool in the investigation of ligand binding has been provided by Gerig.⁴¹

Several efforts have been made recently to provide a theoretical analysis of the effects of the environment on fluorine nuclei, and to explain the chemical shift effects of up to 20 ppm observed when a protein folds about the fluorine indicators.^{42,43} The conclusion has been that the principal influence is via electrostatic interactions, and that this influence is effective in proportion to the magnitude of the paramagnetic term in the nuclear shielding expression.

Fluorine shifts and coupling constants are valuable in the conformational analysis of carbohydrates. Pioneering work in this area was that of Hall.⁴⁴ The spectrum of 6-deoxy-6-fluoro-D-glucose has been carefully analyzed in terms of the conformer population in various solvents; this analysis illustrates the very important point that, although the resonance frequency of ^{19}F is very far removed from that of ^1H , it may represent the X part of a non-first-order system, such as the ABCX system in this molecule, and a first-order interpretation is misleading.⁴⁵

Fluorine-19 has been used as an indicator of the presence of various free ions in living systems. 5-Fluoro derivatives of

the molecule APTRA (*o*-aminophenol-*N,N,O*-triacetic acid) give separate resonances for free and magnesium-bound forms of the indicator, and knowledge of the equilibrium constants involved and the ratios of the two peaks permits evaluation of the free magnesium concentration. The 4-fluoro derivative of APTRA as well as fluorocitrate are in fast exchange with Mg^{2+} , giving a resonance which is at the weighted-average position of the free and magnesium-bound indicator resonances.⁴⁶ Chelators have also been employed to assess calcium concentrations. One, known as 5F RBAPTA, a 1,2-diphenoxyethane derivative, provides slow exchange with Ca^{2+} , and is designed to give rapid spin-lattice relaxation because it contains a *t*-butyl group adjacent to the fluorine.⁴⁷

6 APPLICATIONS OF SPECIAL TECHNIQUES

Two- or three-dimensional ^{19}F correlation spectroscopy provides an attractive means of structure studies, especially for highly fluorinated materials. By firmly establishing coupling connections in a molecule which typically has a very complex spectrum, often with overlapping and non-first-order patterns, these techniques facilitate the relationship of resonances to structural features. COSY has been applied to the assignment of resonances and the study of microstructure of fluorinated polymers.⁴⁸

Figure 2 shows an illustrative COSY spectrum of a mixture of three chlorofluorocarbon isomers. From the one-dimensional ^{19}F spectrum, it was not possible to assign the various multiplets unambiguously or even to be certain that

Figure 2 Homonuclear ^{19}F - ^{19}F COSY (correlation spectroscopy) spectrum of a mixture of three isomers. Formulas of the three components of the mixture are shown and assignments of the resonances are indicated by letters. The spectrometer frequency was 282 MHz. The axes are labeled with arbitrary scales based on the carrier frequency of the spectrometer

the mixture did not contain some six-carbon as well as four-carbon components. Based on inspection of the off-diagonal correlations in the COSY spectrum, combined with consideration of the multiplets in the one-dimensional spectrum and the symmetries of possible components, definitive assignments of structure could be made.

Because of the difficulties of chromatographic resolution of mixtures of isomers of compounds of this type, it is thus very helpful to be able to sort out the resonances belonging to each of the components in a mixture. Hartmann-Hahn-based experiments (HOHAHA or TOCSY) are difficult to apply to a typical fluorinated molecule, especially at the fields now in use, because of the difficulty of maintaining a spin lock over the very wide frequency range required, and a COSY or relayed COSY sequence may be more appropriate.⁴⁹ Even here, however, problems may arise from the spectral widths often encountered, because of the many data points in each dimension required to ensure adequate resolution. Thus selective excitation or selective polarization transfer, such as is possible with the pulse-shaping capabilities of modern instruments, is helpful in reducing the large size of the data arrays required.

By use of appropriate correlation experiments optimized for coupling constants of various magnitudes, it is also possible to determine the relative signs of coupling constants from the sense of the skew in the off-diagonal peaks.⁵⁰

Two-dimensional heteronuclear NOE spectroscopy can be applied to structural studies of ^{19}F -labeled oligodeoxyribonucleotides. In macromolecules, chemical shift anisotropy dominates the spin-spin relaxation of ^{19}F , although T_1 relaxation is primarily dipolar in nature. As a result, the fluorine lines are broad, and small spin-spin couplings to hydrogen cannot be resolved. Since the Overhauser enhancement ratio for ^{19}F - $\{^1\text{H}\}$ in a large molecule is -1 , this technique affords a means of determining spatial adjacencies.⁵¹

In fluorine-labeled molecules such as steroids, there may be many proton spin-spin interactions with the label atom, and it is experimentally difficult to unravel the splittings in the fluorine spectrum by selective decoupling of protons. Two-dimensional heteronuclear correlation experiments, analogous to homonuclear COSY, can be used to establish long-range couplings, from which conformational information can be obtained.⁵² In a number of steroids, small splittings caused by protons remained unresolved in the proton spectrum because of their number and the widths of the lines. In COSY, all interactions down to the limit imposed by the intrinsic linewidth can be resolved, and long-range couplings of 0.5 Hz or less are observable. Combining the information from the coupling constants with known effects on chemical shifts made it possible to assign the NMR spectra completely and to derive complete steroid structures.

As another means to establish connectivities, one might examine the proton spectrum with the fluorine decoupled; in the absence of a fluorine decoupler, this has been done by using the proton decoupler as the source of the observe signal and pulsing the fluorine signal from the transmitter between the acquisition intervals in the FID. Both COSY and one-dimensional experiments have been performed in this way.⁵³

Finally, an alternative approach to unraveling complex fluorine-proton interactions involves the use of fluorine decoupling achieved by a spin-flip technique. The output of two channels of a dual-channel spectrometer is combined and

applied to the high-frequency coil in a probe. During the period of acquisition of the proton signals, pulses from the fluorine channel, applied in the empty time slots, are phase cycled according to an XY-4 or XY-32 scheme, spreading the irradiation frequency over the needed wide bandwidth.⁵⁴

1 INTRODUCTION

The NMR properties of germanium, tin and lead are listed in Table 1. Except for ^{73}Ge ($I = \frac{9}{2}$), all NMR-active nuclides in Group 14 possess spin $I = \frac{1}{2}$. As a consequence of a medium quadrupolar moment, $Q(^{73}\text{Ge})$, ^{73}Ge NMR signals become rather broad if the charge distribution around the germanium atom is nonspherical. Therefore, chemical shifts $\delta^{73}\text{Ge}$ have been determined just for a few classes of compounds. Only a limited number of coupling constants involving ^{73}Ge is accessible, and many important NMR techniques for elucidating structure and bonding cannot be applied in the case of ^{73}Ge NMR. In contrast, tin and lead NMR are ideal tools for studying the chemistry of these elements. Whereas there is only one lead isotope (^{207}Pb) with $I = \frac{1}{2}$, there are three spin- $\frac{1}{2}$ isotopes of tin (^{115}Sn , ^{117}Sn , ^{119}Sn) of which two (^{117}Sn , ^{119}Sn) have an appreciable natural abundance. Owing to its slightly greater magnetic moment ^{119}Sn NMR is usually preferred for NMR measurements.

In principle it should be easy to measure ^{73}Ge NMR in the pulse Fourier transform (PFT) mode by the application of single $\pi/2$ pulses, using a very short delay between consecutive experiments, as the quadrupolar relaxation rate of the ^{73}Ge nuclides is fast in almost all cases. However, ^{73}Ge NMR suffers from the combined effects of broadened resonance signals and of the low ^{73}Ge resonance frequency. The latter is responsible for low NMR sensitivity hampering CW experiments and, in the PFT mode, acoustic ringing induces severe distortion of the baseline¹ ('rolling baseline') which makes the assignment of broad NMR signals very difficult. A number of pulse sequences have been developed to eliminate the influence of acoustic ringing,² most of which, however, introduce other limitations. The most efficient experiments include the application of composite pulses³ and this enables the use of larger spectral windows for the observation of broad lines.^{4,5} There are still many problems in measuring ^{73}Ge NMR, and the broadest lines observed possess linewidths in the order of 600 Hz.

The negative sign of $\gamma(^{119}\text{Sn})$ causes a negative NOE (see **Nuclear Overhauser Effect**) which may cancel or severely reduce the intensity of ^{119}Sn NMR signals if dipolar interactions play an important role in ^{119}Sn nuclear relaxation.

In this case it is advisable to use inverse gated ^1H decoupling. Otherwise, polarization transfer techniques (INEPT,⁶ DEPT⁷) can be applied to circumvent this problem. Before PFT NMR became available, ^{119}Sn NMR was measured in the CW mode, most frequently by $^1\text{H}\{^{119}\text{Sn}\}$ heteronuclear double resonance experiments (INDOR) if ^{119}Sn – ^1H scalar couplings were present.⁸ Nowadays, modern PFT spectrometers can be used for 2D ^1H -detected (inverse) ^1H – ^{119}Sn correlated spectroscopy in order to record ^{119}Sn NMR signals of dilute solutions and/or of broad ^{119}Sn resonances.⁹ All multidimensional NMR techniques, originally developed for ^{13}C NMR, can also be applied to ^{119}Sn NMR. The presence of ^{119}Sn and ^{117}Sn in molecules containing two or more tin atoms allows the measurement of coupling constants $^nJ(\text{Sn}, \text{Sn})$ even for tin atoms which are chemically equivalent.^{10,11} ^{119}Sn NMR is also an attractive method for studying solids, either of static samples, or by MAS or CP MAS methods because of the appreciable ^{119}Sn NMR sensitivity.

With modern instruments ^{207}Pb NMR spectra from solutions are readily measured^{10,12} and the same techniques can be applied as outlined for ^{119}Sn NMR. In solid state ^{207}Pb NMR, the huge anisotropy of the ^{207}Pb nuclear shielding may pose a problem. This can be overcome by using faster spinning speeds in MAS experiments (which however may reduce the CP efficiency) or by measuring the spectra at lower field strength B_0 .

2 CHEMICAL SHIFTS $\delta^{73}\text{Ge}$, $\delta^{119}\text{Sn}$, AND $\delta^{207}\text{Pb}$

2.1 General Remarks

The most extensive data set is available for $\delta^{119}\text{Sn}$ ^{10,11,13} (range: $\approx +3000$ to -2500), followed by $\delta^{207}\text{Pb}$ ^{10,12,13} (range: $\approx +10\,000$ to -6000) and a small data set of $\delta^{73}\text{Ge}$ ¹⁴ has been collected. For all three nuclides the tetramethyl derivatives, Me_4M ($\text{M} = ^{73}\text{Ge}$, ^{119}Sn , ^{207}Pb), or better the corresponding frequencies $\Xi(\text{M})$ (see Table 1), serve as an external reference. The temperature dependence of δ_{M} can be significant in the case of $\text{M} = ^{119}\text{Sn}$ and, in particular, for $\text{M} = ^{207}\text{Pb}$ according to the greater range of chemical shifts. The same is true for solvent effects which may become rather large if there is a direct chemical interaction between the solvent and the compounds under investigation. In general, we find a dependence of nuclear shielding on the coordination number (CN): an increase in the value of CN causes increased nuclear shielding. This is exactly the same trend that has been observed for ^{29}Si nuclear shielding, amplified by the factor governed by the change in the radial term $\langle r^{-3} \rangle_{np}$ where r is the expected radius for an electron in the np orbital. In the case of ^{207}Pb nuclear shielding, relativistic effects may complicate this otherwise rather consistent pattern.

There are close to linear relationships between δM values ($\text{M} = ^{29}\text{Si}$, ^{73}Ge , ^{119}Sn , ^{207}Pb) of isostructural compounds [see equation (1),¹⁵ equation (2),¹⁵ and equation (3)¹³].

$$\delta^{73}\text{Ge} = 3.32 \times \delta^{29}\text{Si} + 39.9 \quad (29; r = 0.967) \quad (1)$$

$$\delta^{119}\text{Sn} = 1.56 \times \delta^{73}\text{Ge} - 87.4 \quad (26; r = 0.991) \quad (2)$$

$$\delta^{207}\text{Pb} = 2.43 \times \delta^{119}\text{Sn} + 34 \quad (40; r = 0.996) \quad (3)$$

Table 1 NMR Properties of Group 14 Elements

	Spin <i>I</i>	N. A. ^a (%)	<i>Q</i> (10 ⁻²⁸ m ²)	γ (10 ⁷ rad s ⁻¹ T ⁻¹)	Ξ (MHz)	Reference compound
¹³ C	$\frac{1}{2}$	1.108	—	6.7283	25.145 004	Me ₄ Si
²⁹ Si	$\frac{1}{2}$	4.70	—	-5.3190	19.867 184	Me ₄ Si

^aNatural abundance

The comparison of $\delta^{119}\text{Sn}$ and $\delta^{207}\text{Pb}$ values of tin(II) and lead(II) derivatives shows a different type of correlation [equation (4)¹³] which, in the case of stannocenes and plumbocenes, merges with the relationship between δM of tin(IV) and lead(IV) compounds [equation (3)]. The greater slope and the large intercept in equation (4) as compared with equation (3) point towards relativistic effects,^{16,17} connected with the nature of the lone pair of electrons.

$$\delta^{207}\text{Pb} = 3.30 \times \delta^{119}\text{Sn} + 2336 \quad (20; r = 0.998) \quad (4)$$

In the case of $CN = 4$, substituent effects can be used in an empirical way for the prediction of δM . Similarly, the concept of pairwise additive parameters¹⁸ can be applied. The normal halogen dependence of δM is found (highest M nuclear shielding in MI_4). There is no direct relationship between δM and the substituent electronegativity if the substituent is linked directly to M. However, electronegative substituents other than fluorine which are removed from M by more than one bond may cause deshielding. Differing bond angles at M are expected to affect nuclear shielding. The comparison between δM values, if M is part of a five- or six-membered ring, indicates that significant deshielding of M ($\Delta^{73}\text{Ge} \approx 50 \text{ ppm}$;^{14,19} $\Delta^{119}\text{Sn} \approx 100 \text{ ppm}$;²⁰ $\Delta^{207}\text{Pb} \approx 200\text{--}250 \text{ ppm}$ ²¹) always occurs in the five-membered ring.

2.2 Application of $\delta^{73}\text{Ge}$

Since the successful detection of ⁷³Ge NMR signals depends heavily on the quadrupolar relaxation rate, $\delta^{73}\text{Ge}$ values are not likely to be determined in routine experiments. Although mixtures (e.g., of germanium tetrahalides^{15,22} or isomeric germacyclohexanes²³) have been analyzed by ⁷³Ge NMR, and $CN(\text{Ge}) > 4$ has been proved by increased ⁷³Ge nuclear shielding²⁴ (Figure 1), the expected (vide supra) limitations because of the unfavorable NMR properties are obvious.

**Figure 1** Chemical shift data, $\delta^{73}\text{Ge}$, for isomeric germacyclohexanes, and $CN(\text{Ge}) = 7$ and 6

2.3 Application of $\delta^{119}\text{Sn}$

Chemical shifts $\delta^{119}\text{Sn}$ serve in numerous ways in tin chemistry. All reactions of tin compounds can be monitored by ¹¹⁹Sn NMR under realistic conditions, in rather dilute solutions and in nondeuterated solvents. Intermediates and products are characterized by typical $\delta^{119}\text{Sn}$ data, taking advantage of the large data set available.^{10,11} Examples are shown in Figures 2 and 3. A typical application of $\delta^{119}\text{Sn}$ values concerns the study of exchange reactions²⁵ which may lead to numerous compounds which cannot be isolated but can readily be identified on the basis of their $\delta^{119}\text{Sn}$ values (see Figure 4).

Extreme ¹¹⁹Sn nuclear deshielding is found in monomeric dialkylstannylenes as a result of low energy $\sigma-\pi^*$ and $n-\pi^*$ transitions (Figure 5). In analogous bis(amino)stannylenes the ¹¹⁹Sn nuclides are better shielded because of the influence of the electronegative nitrogen atoms on these transitions. Dimerization via the Sn–Sn bond or via coordinate N–Sn bonds leads to a significant increase in ¹¹⁹Sn nuclear shielding (e. g. in $[(\text{Me}_3\text{Si})_2\text{CH}]_2\text{Sn}=\text{Sn}[\text{CH}(\text{SiMe}_3)_2]_2$ with $\delta^{119}\text{Sn} = +740$ and $+725$ ²⁷ for the two conformers, and in $[\text{Me}_2\text{Si}(\text{N}^i\text{Pr})_2\text{Sn}]_2$ with $\delta^{119}\text{Sn} = +202$ ²⁸). This shows that any type of association of tin compounds can be studied most conveniently by ¹¹⁹Sn NMR.

The electronic structure of Zintl anions (another class of compounds in which tin is formally in a low oxidation state) of the type $[\text{Sn}_4]^{2-}$ ($\delta^{119}\text{Sn} = -1895$ ²⁹), $[\text{Sn}_9]^{4-}$ ($\delta^{119}\text{Sn} = -1230$ ³⁰) $[\text{Sn}_8\text{Ti}]^{5-}$ ($\delta^{119}\text{Sn} = -1167$ ²⁹) or $[\text{Sn}_{9-n}\text{Pb}_n]^{4-}$ ($n = 1\text{--}8$; $\delta^{119}\text{Sn} = -1270$ to -1600 ³⁰) is reflected by the fairly high ¹¹⁹Sn nuclear shielding in these highly fluxional cluster anions.

As shown in Figure 6, extreme ¹¹⁹Sn nuclear shielding is typical of stannocenes,¹¹ both for a parallel³¹ and bent arrangement^{32,33} of the cyclopentadienyl rings. The high ¹¹⁹Sn nuclear shielding also prevails in heterostannocenes.³⁴

With few exceptions [e.g., $\delta^{119}\text{Sn}$ of $\text{Sn}(\text{C}\equiv\text{CR})_4$, -350 to -380] $\delta^{119}\text{Sn}$ values of tin(IV) compounds with $CN(\text{Sn}) = 4$ are found in the range between $+200$ and -200 .¹¹ A marked deshielding influence can be exerted if transition metals are linked to the tin atom, and, in particular, if multicenter bonding has to be taken into account, e.g. in $\text{Sn}[\text{Fe}(\text{CO})_4]_4$ with $\delta^{119}\text{Sn} = +1532$.³⁵

Solid state ¹¹⁹Sn NMR spectra of a great variety of tin compounds have been studied which reveal important information on structural changes as compared with solutions, in particular if direct structural information from X-ray analysis is available. Representative examples are organotin

Figure 2 The 1,1-organoboration of $\text{Me}_2\text{Sn}(\text{C}\equiv\text{CBu})_2$ with Et_3B (ratio 1:1.4):⁷³ 33.3 MHz ^{119}Sn NMR (^1H inverse gated decoupled) at 203 K, 283 K, and 298 K. At 203 K, the ^{119}Sn NMR signal of the starting material, $\text{Me}_2\text{Sn}(\text{C}\equiv\text{CBu})_2$, can still be detected together with a signal for a bis(alkenyl)tin compound, and a strong signal appears for a zwitterionic intermediate. No starting material is left at 283 K, and at 298 K the zwitterionic intermediate has partially rearranged into a stannole derivative and a 1-stanna-4-bora-2,5-cyclohexadiene (see Figure 3 for further changes). Note the extreme temperature sensitivity of the ^{119}Sn NMR signal of the zwitterionic intermediate, indicating a dynamic equilibrium in which the bridging alkynyl group migrates between boron and tin

halides,³⁶ organotin chalcogenides,^{37,38} stannocenes,^{31–33} and various other cyclic and noncyclic organotin compounds.^{39–41}

2.4 Application of $\delta^{207}\text{Pb}$

In principle, applications of $\delta^{207}\text{Pb}$ values are similar to those of $\delta^{119}\text{Sn}$. As a result of the greater range of $\delta^{207}\text{Pb}$ values,^{12,13} these data are extremely sensitive to small changes in the surrounding of the lead atom. Extreme ^{207}Pb nuclear deshielding is observed for the monomeric plumbylene $[(\text{Me}_3\text{Si})_2\text{CH}]_2\text{Pb}$ ($\delta^{207}\text{Pb} = +9110$ ⁴²) which apparently, in contrast to the analogous tin compound, is not in equilibrium with its dimer. The $\delta^{207}\text{Pb}$ values of monomeric bis(amino)plumbylenes are close to +5000 (e.g., $[(\text{Me}_3\text{Si})_2\text{N}]_2\text{Pb}$ with $\delta^{207}\text{Pb} = +4916$). The increased ^{207}Pb nuclear shielding in Zintl anions $[\text{Pb}_{9-n}\text{Sn}]^{4-}$ ($n = 1–8$; $\delta^{207}\text{Pb} = -3932$ to -2667 ³⁰) also corresponds to the $\delta^{119}\text{Sn}$ data. Similarly, high ^{207}Pb nuclear shielding is found for plumbocenes (e.g., $(\eta^5\text{-Me}_5\text{C}_5)_2\text{Pb}$ with $\delta^{207}\text{Pb} = -4390$ ³² or $(\eta^5\text{-Ph}_5\text{C}_5)_2\text{Pb}$ with $\delta^{207}\text{Pb} = -6150$ ³¹).

The majority of $\delta^{207}\text{Pb}$ values for lead (IV) compounds with $\text{CN}(\text{Pb}) = 4$ is found in the range between +500 and -800 ppm. This includes compounds of the type $\text{Pb}(\text{C}\equiv\text{CR})_4$ (e.g., $\text{R} = \text{Me}$ in CDCl_3 , $\delta^{207}\text{Pb} = -687.0$ ⁴³) and $\text{Pb}(\text{CF}_3)_4$ ($\delta^{207}\text{Pb} = -562.2$ ⁴⁴). Any kind of association is readily

reflected by $\delta^{207}\text{Pb}$ data as shown for example in the case of the self-association of Me_3PbOMe , depending on concentration, and in the solid state with $\text{CN}(\text{Pb}) = 5$ ⁴⁵ (Figure 7).

The different ^{207}Pb nuclear shielding in solid Me_3PbOMe as compared with solutions indicates important applications of solid state ^{207}Pb NMR. There are also many applications to inorganic solids.¹²

3 INDIRECT NUCLEAR SPIN–SPIN COUPLING CONSTANTS

3.1 General Remarks

The signs of numerous coupling constants $^nJ(\text{M},\text{X})$ have been determined, mainly by application of heteronuclear double resonance techniques in 1D and 2D NMR experiments. Examples are given in Table 2. For the comparison of coupling constants involving different nuclides it is advisable to use the reduced coupling constants nK [equation (5)] instead of nJ in order to eliminate the individual magnetic properties of the nuclides.

$$^nK(\text{M},\text{X}) = 4\pi^2 \cdot ^nJ(\text{M},\text{X}) \cdot (h\gamma_{\text{M}}\gamma_{\text{X}})^{-1} \quad (5)$$

Figure 3 The 1,1-organoboration of $\text{Me}_2\text{Sn}(\text{C}\equiv\text{CBu})_2$ with Et_3B (ratio 1:1.4).⁷³ (a) 33.3 MHz ^{119}Sn NMR (^1H inverse gated decoupled) of the reaction mixture which is formed immediately after warming to 298 K. (b) The same mixture after 24 h at 298 K. Note the significant change in intensity of two ^{119}Sn NMR signals: a stannolene derivative is formed at the expense of the noncyclic bis(alkenyl)tin compound

Figure 4 74.6 MHz ^{119}Sn NMR spectrum (^1H inverse gated decoupled) of an equilibrated mixture of $(\text{Me}_2\text{SnS})_3$ (1) and $(\text{Me}_2\text{SnSe})_3$ (4) in CHCl_3 . The formation of the 'mixed' six-membered rings (2) and (3) is shown.¹¹ The weak signals are $^{117}/^{119}\text{Sn}$ satellites (close to the parent signals) and ^{77}Se satellites (some are hidden in the range of the central lines)

Figure 5 Chemical shift data, $\delta^{119}\text{Sn}$, for monomeric dialkylstannylenes and bis(amino)stannylenes

$(\eta^5\text{-R}_5\text{C}_5)_2\text{Sn}$					$(\eta^5\text{-2,5-}^t\text{Bu}_2\text{C}_4\text{N})_2\text{Sn}$				
R	H ³³	Me ³²	Bz ³¹	Ph ³¹					
$\delta^{119}\text{Sn}$	-2199	-2129	-2188	-2215	-1889 ³⁴				

Figure 6 Chemical shift data $\delta^{119}\text{Sn}$, for stannocenes and a 1,1'-diazastannocene

When the signs of $^nK(^{29}\text{Si},\text{X})$ and $^nK(^{119}\text{Sn},\text{X})$ have been determined to be the same, it can be safely assumed that $^nK(^{73}\text{Ge},\text{X})$ has the same sign. In contrast, the sign of $^nK(^{207}\text{Pb},\text{X})$ may change more readily, and it has to be

$\text{Me}_3\text{Pb}-\text{OMe}$				
Concentration (mol l ⁻¹), 27 °C, in CDCl ₃	0.16	0.40	1.18	Solid state
$\delta^{207}\text{Pb}$ (ppm)	+391.2	+379.9	+307.5	+103.8

Figure 7 Dependence of $\delta^{207}\text{Pb}$ values on the degree of self-association in trimethyllead methoxide

determined, in particular if an unusual trend of the values $^nK(^{207}\text{Pb},\text{X})$ becomes apparent.

It appears that the Fermi contact term is the dominating mechanism for electron mediated nuclear spin–spin coupling.⁴⁶ Accordingly, the sign and magnitude of one-bond coupling constants $^1J(\text{M},\text{X})$ ($\text{M} = ^{73}\text{Ge}, ^{119}\text{Sn}, ^{207}\text{Pb}$) depend on the valence s electron densities, $S(0)_\text{M}^2$ and $S(0)_\text{X}^2$, and on the mutual polarizability term, Π_{MX} , which involves the energies of the ground and excited electronic states and the s overlap integral of the bond between the two nuclides. At least in the case of ^{207}Pb , relativistic effects may become important because of spin–orbit splitting of non-s shells and because of the contraction of s and p shells.¹⁶

Table 2 Some Coupling Constants $^1J(\text{M},\text{X})$ (Hz) and Reduced Coupling Constants $^1K(\text{M},\text{X})$ ($10^{20}\text{ N A}^{-2}\text{ m}^{-3}$) ($\text{M} = ^{29}\text{Si}, ^{49}\text{Ti}, ^{119}\text{Sn}, ^{11}\text{B}, ^{207}\text{Pb}$)

_an.o. = not observed.

As for other geminal reduced coupling constants $^2K(\text{A}, \text{X})$, a fairly large range is observed for $^2K(\text{M}, \text{X})$ [e.g., $|^2J(^{119}\text{Sn}, ^{119}\text{Sn})| \approx 0$ to 35 000 Hz], and both positive and negative signs have been determined.^{10, 11} The magnitude and sign of $^2K(\text{M}, \text{X})$ depends in the usual way on the nature of the intervening atom E, the bond angle M–E–X, and on effects exerted by substituents linked to M, E, and X.⁴⁶ In the case of the vicinal reduced coupling constants $^3K(\text{M}, \text{X})$ across E–E' bonds (e.g. E = E' = C), there is a dependence on the dihedral angle Φ (M–E–E'–X) [a positive sign of $^3K(\text{M}, \text{X})$ with a minimum of $^3K(\text{M}, \text{X})$ for $\Phi = 90^\circ$ and maxima for $\Phi = 0$ and 180°] which appears to be generally valid.⁴⁶ The influence of substituents on $^3K(\text{M}, \text{X})$ corresponds to that found for many other values $^3K(\text{A}, \text{X})$.

As a result of the increase in $S(0)^2_{\text{M}}$, as compared to lighter nuclides, many long-range coupling constants $^nJ(\text{M}, \text{X})$ ($n > 3$; M = ¹¹⁹Sn, ²⁰⁷Pb) have been measured. At present, systematic trends have been observed only for a few classes of compounds such as alkynes ($n = 4$)⁴⁷ or allenes ($n = 4, 5$).⁴⁸

3.2 Coupling Constants Involving ⁷³Ge

As a result of efficient ⁷³Ge quadrupolar relaxation, ⁷³Ge–X spin–spin coupling can be observed only in the case of symmetrical charge distribution around ⁷³Ge. So far examples are limited to X = ¹H, ¹³C and ¹⁹F (see Table 3 for representative examples).

3.3 Coupling Constants Involving ¹¹⁹Sn

The magnitude of the coupling constants $^1J(^{119}\text{Sn}, ^1\text{H})$ in SnH₄ (−1930 Hz⁵⁰) and in organotin hydrides R_{3–n}SnH_n ranges from ≈ -1500 to ≈ -1900 Hz [$^1K(^{119}\text{Sn}, ^1\text{H}) > 0$], increasing in absolute magnitude with increasing number n , and depending on the group electronegativity of R, is completely in accord with the model of rehybridization⁵¹ at the tin atom. There is also a wealth of data for $^2J(^{119}\text{Sn}, ^1\text{H})$ and $^3J(^{119}\text{Sn}, ^1\text{H})$, many of which are useful in structural assignments.

Except for tin(II) compounds (R₂Sn)¹³ and triorganotin anions ([R₃Sn][−]),⁵² it holds that all $^1J(^{119}\text{Sn}, ^{13}\text{C}) < 0$ [$^1K(^{119}\text{Sn}, ^{13}\text{C}) > 0$]. The 's character' of the Sn–C hybrid

Me _{4–n} Sn(C≡C–SiMe ₃) _n	$n = 0$	1	2	3	4
$ ^1J(^{119}\text{Sn}, ^{13}\text{CMe}) $ (Hz)	340.0	402.6	489.1	603.7	—
$ ^1J(^{119}\text{Sn}, ^{13}\text{C}\equiv) $ (Hz)	—	398.0	552.5	760.0	1036.0

Figure 8 Comparison of the coupling constants between ¹¹⁹Sn and sp³- and sp-hybridized ¹³C nuclides

orbitals can be used to explain changes in $|^1J(^{119}\text{Sn}, ^{13}\text{C})|$, at least in the case of tetraalkyltin compounds. However, the data for alkynyltin compounds indicate that the situation may be much more complex, since in R₃Sn–C≡C–R¹ (e.g., R = alkyl, R¹ = alkyl, aryl, SiMe₃, SnR₃), in spite of the sp-hybridized carbon atom, the magnitude of $|^1J(^{119}\text{Sn}, ^{13}\text{C}\equiv)|$ is frequently smaller than $|^1J(^{119}\text{Sn}, ^{13}\text{C}_R)|$. This shows that the electropositive tin atom is readily polarized by an electronegative ligand, and such polar Sn–C≡ bonds give rise to negative contributions to the Fermi contact term. The polarizability of the tin atom is reduced in the presence of more electronegative groups. Therefore, as shown in Figure 8, the magnitude of $|^1J(^{119}\text{Sn}, ^{13}\text{C}\equiv)|$ becomes 'normal' in di-, tri-, and tetra-1-alkynyltin compounds.⁵³

Because of the readily polarizable tin atoms, the magnitude of $^1J(^{119}\text{Sn}, ^{119}\text{Sn})$ ranges from negative values in anions to rather large and presumably positive values in distannanes with CN(Sn) = 5. Examples are depicted in Figure 9. A large data set exists for $^2J(\text{Sn}, \text{Sn})$. These data are particularly useful in the characterization of transition metal complexes with more than one SnCl₃ ligand.¹¹ The detection of ¹¹⁷Sn satellites in ¹¹⁹Sn NMR spectra proves that intermolecular exchange must be slow compared with the NMR timescale, and the intensities of the ¹¹⁷Sn satellite signals enable the determination of the number of SnCl₃ groups present.

The sign of $^1J(^{119}\text{Sn}, ^{15}\text{N})$ changes, in most cases, from negative to positive in the series of Me_{4–n}Sn(NR₂)_n for $n > 1$. For $n = 1$, Hahn echo extended (HEED) pulse sequences⁵⁸ (e.g., INEPT-HEED or DEPT-HEED) are most convenient for the determination of $^1J(^{119}\text{Sn}, ^{15}\text{N})$ and the isotope-induced chemical shifts $^1\Delta^{15/14}\text{N}(^{119}\text{Sn})$. In cases with fairly large scalar coupling $^2J(^{119}\text{Sn}, ^{14}\text{N})$, this technique can also be applied, as shown for 2-(trimethylstannyl)pyridine in Figure 10.

Figure 9 Change of sign for coupling constants $^1J(^{119}\text{Sn}, ^{119}\text{Sn})$

Figure 10 186.5 MHz ^{119}Sn NMR spectrum of 2-(trimethylstannyl)pyridine⁷⁴ (5 mm tube; $\approx 20\%$ v/v in C_6D_6 ; 25°C ; 64 scans; pulse repetition delay 5 s) recorded by using the refocused INEPT-HEED pulse sequence⁵⁸ with a Hahn echo delay of 10 ms. The broad parent ^{119}Sn NMR signal represents the ^{119}Sn – ^{14}N isotopomer, broadened by partially relaxed ^{119}Sn – ^{14}N scalar coupling. The ^{15}N satellites [$^1J(^{119}\text{Sn}, ^{15}\text{N}) = 108.2\text{ Hz}$] are marked by asterisks

A positive sign of $^1J(^{119}\text{Sn}, ^{31}\text{P})$ [$^1K(^{119}\text{Sn}, ^{31}\text{P}) < 0$] has been found in stannylphosphanes, whereas $^1J(^{119}\text{Sn}, ^{31}\text{P})$ is large and negative in phosphane– SnCl_4 adducts⁵⁹ [e.g., $(\text{Bu}_3\text{P})_2\text{SnCl}_4$ with $^1J(^{119}\text{Sn}, ^{31}\text{P}) = 2550\text{ Hz}$]. In transition metal complexes (Figure 11) the magnitude of $^1J(^{119}\text{Sn}, ^{31}\text{P})$ is also reduced [$^1K(^{119}\text{Sn}, ^{31}\text{P})$ becomes less negative], since the lone pair of electrons at the phosphorus atom is engaged in M–P bonding.⁶⁰

In transition metal complexes with metal–tin bonds, rather large values for ^{119}Sn –metal coupling constants (e.g.,

$^1J(^{119}\text{Sn}, ^{31}\text{P})$ (Hz)			
$(\text{Me}_3\text{Sn})_3\text{P}$	+832.5	$(\text{Me}_3\text{Sn})_3\text{P}-\text{W}(\text{CO})_5$	+375.5
$\text{Me}_3\text{SnPPh}_2$	+586.0	$\text{Me}_3\text{SnPPh}_2-\text{W}(\text{CO})_5$	+50.0

Figure 11 Comparison between coupling constants $^1J(^{119}\text{Sn}, ^{31}\text{P})$ in stannylphosphanes and their pentacarbonyl tungsten complexes

metal = ^{183}W , ^{103}Rh , ^{195}Pt) are observed. In particular, in metal– SnCl_2 ⁶¹ and metal– SnCl_3 complexes,^{62,63} these data are indicative of the kinetic stability of the Sn–metal bond.

Interestingly, coupling constants between tin and quadrupolar nuclei can be frequently observed more easily in solid state ^{119}Sn NMR spectra as compared to NMR in solution. Typical examples include $^1J(^{119}\text{Sn}, ^{11}\text{B})$,⁹ $^1J(^{119}\text{Sn}, ^{35}\text{Cl})$,³⁶ and even $^1J(^{119}\text{Sn}, ^{39}\text{K})$.⁶⁴

3.4 Coupling Constants Involving ^{207}Pb

The general trend of all ^{207}Pb –element coupling constants follows that observed for ^{119}Sn , although the sign of $^1J(^{207}\text{Pb}, \text{X})$ changes much more readily than that of $^1J(^{119}\text{Sn}, \text{X})$. This is shown by the correlation between $^1J(^{207}\text{Pb}, ^{13}\text{C})$ and $^1J(^{119}\text{Sn}, ^{13}\text{C})$ of methyllead and methyltin compounds in equation (6).

$$^1J(^{207}\text{Pb}, ^{13}\text{C}_{\text{Me}}) = -2.26 \ ^1J(^{119}\text{Sn}, ^{13}\text{C}_{\text{Me}}) - 556.6 \quad (r = 0.985) \quad (6)$$

Sign inversion of $^1J(^{207}\text{Pb}, ^{13}\text{C})$ has been observed in alkynyllead compounds,^{43,65} in trimethylplumbyl methane derivatives,⁶⁶ and also in the series of trifluoromethyl derivatives $(\text{CF}_3)_{4-n}\text{PbR}_n$ ($n = 0-3$; $\text{R} = \text{Me}, \text{Et}$).⁴⁴ There is even one example with a positive and a negative sign for $^1J(^{207}\text{Pb}, ^{13}\text{C}_{\text{Me}})$ in the same molecule⁶⁵ (Figure 12). Negative contributions to the Fermi contact term arise because of the large polarizability of the lead atom and, in addition, relativistic effects are likely to become important. This is obvious by comparing the reduced coupling constants $^1K(^{207}\text{Pb}, \text{M})$ ($\text{M} = ^{119}\text{Sn}, ^{207}\text{Pb}$) in $\text{Me}_3\text{Pb}-\text{MMe}_3$ (see Table 2). A number of hexaaryldiplumbanes has been studied with respect to $^1J(^{207}\text{Pb}, ^{207}\text{Pb})$,⁶⁷ and in some cases $^1J(^{207}\text{Pb}, ^{207}\text{Pb})$ can be determined from solid state ^{207}Pb CP MAS NMR spectra.⁶⁸ Large negative values of $^1K(^{207}\text{Pb}, ^{15}\text{N})$ and $^1K(^{207}\text{Pb}, ^{31}\text{P})$ are common (see Table 2).

4 NUCLEAR SPIN RELAXATION PARAMETERS

4.1 ^{73}Ge Nuclear Spin Relaxation in Solution^{14, 15, 22}

The spin–lattice relaxation time $T_1(^{73}\text{Ge})$ is dominated by quadrupolar relaxation, even in the case of the species GeR_4 ($\text{R} = \text{organyl}$) or GeX_4 ($\text{X} = \text{halogen}$) with tetrahedral surrounding of the germanium atom. This is the result of the interaction

Figure 12 The signs of the coupling constants $^1J(^{207}\text{Pb}, ^{13}\text{C}_{\text{Me}})$ are different, although the methyl groups are linked to the same lead atom. Note the small difference between the geminal coupling constants $^2J(^{207}\text{Pb}, ^1\text{H}_{\text{Me}})$

between the quadrupole moment (eQ) and the electric field gradient (eq) which is modulated by molecular motion. In general it holds that $T_1^{73\text{Ge}} \geq T_2^{73\text{Ge}}$. The transverse relaxation time $T_2^{73\text{Ge}}$ may be further shortened by scalar interactions such as scalar coupling with other quadrupolar nuclides [e.g., $^1J(^{73}\text{Ge}, ^{35/37}\text{Cl})^{69}$]. The longest $T_1^{73\text{Ge}}$ values are in the order of ≤ 0.5 s (e.g. in GeMe_4 and in GeCl_4 depending in the usual way on concentration, solvent, and temperature). In other compounds GeR_4 , with larger groups R, the $T_1^{73\text{Ge}}$ values become shorter, as expected for longer rotational correlation times τ_c .

4.2 ^{119}Sn and ^{207}Pb Nuclear Spin Relaxation in Solution

As for other spin- $\frac{1}{2}$ nuclides, various relaxation mechanisms are expected to compete in ^{119}Sn ^{10,11,13,70} or ^{207}Pb nuclear relaxation.^{10,12,13,71} Dipole–dipole (DD) interactions between ^{119}Sn and ^1H have to be taken into account (negative NOE in ^1H broadband decoupled spectra!) even in the case of medium-size molecules ($\text{MW} < 1000$) and, in particular, for measurements at low temperature. The other important relaxation mechanism are spin–rotation (SR) and scalar interactions (SC), the latter being significant for $T_2^{119\text{Sn}}$ or $T_2^{207\text{Pb}}$ (increase in the linewidths of ^{119}Sn or $^{207\text{Pb}}$ NMR signals)—a result of partially relaxed scalar coupling with quadrupolar nuclides [e.g., ^{11}B (see Figure 13), ^{14}N (see Figure 10), ^{35}Cl , ^{37}Cl , ^{79}Br , ^{81}Br , etc.]. In many cases of fairly small molecules, e.g. in MR_4 ($\text{M} = \text{Sn}$, Pb), the SR mechanism is of major importance. If the symmetry about M is reduced, the relaxation mechanism based on chemical shift anisotropy (CSA) has to be considered. Since the efficiency of this mechanism increases with B_0^2 , it is frequently found with modern high-field NMR spectrometers ($B_0 \geq 4.7$ T) that the CSA mechanism is dominant for ^{207}Pb nuclear spin relaxation if the local symmetry at the lead atom is reduced.

Figure 13 93.3 MHz ^{119}Sn NMR spectrum (^1H inverse gated decoupled) of a 1,1-bis(trimethylstannyl)alkenyltin compound ($\text{R} = N$ -pyrrolyl) showing ^{119}Sn and ^{117}Sn satellites [marked by asterisks and arrows, respectively; $^2J(^{119}\text{Sn}, ^{119}\text{Sn}) = 885.5$ Hz] and rather different linewidths owing to partially relaxed vicinal ^{119}Sn – ^{11}B scalar coupling: $-^3J(^{119}\text{Sn}, ^{11}\text{B})$ —*trans* (≈ 73 Hz) $>$ $-^3J(^{119}\text{Sn}, ^{11}\text{B})$ —*cis* (≈ 41 Hz)⁷⁵

The competition between various relaxation mechanisms has been demonstrated in the case of some monomeric tin(II) and lead(II) compounds.^{13,72}

1 INTRODUCTION

By any measure, H₂ is one of the simplest molecules. Hence, it is remarkable how many surprises and unusual phenomena appear in the NMR of the hydrogens. This article will describe the surprises.

At the outset, it should be noted that hydrogen NMR signals from the liquid and solid phases are particularly strong. The density of protons in liquid H₂ is only 20% less than that in water; near the freezing point of 14 K, the Boltzmann factor is 20 times larger for H₂ than for room temperature H₂O. Partly because of the large signals, H₂ was studied early in the history of NMR.^{1,2} With such a large spin magnetization come the so-called radiation damping (or radiation reaction) effects³ (see *Concentrated Solution Effects*).

One of the unique features of hydrogen NMR is that a quantum description of the molecular orientation and rotation is required. Furthermore, H₂ remains ‘lively’ (molecular reorientations still rapid) at low temperatures, where most other systems are completely frozen, except for small-amplitude vibrations. The existence of the several isotopic forms H₂, HD, and D₂ (and radioactive HT, DT, and T₂) is also unusual; the large mass ratios can cause large isotope effects.

Part of this article is concerned with hydrogen molecules in inert matrices or physically adsorbed on a substrate. But first the subject will be placed in proper perspective by describing the behavior of solid H₂ (in particular, the lineshape) and gaseous H₂ (in particular, the relaxation mechanism), after a short discussion of the molecular properties.

2 PROPERTIES OF HYDROGEN MOLECULES

A clear, thorough overview of the physical properties of liquid and solid hydrogen, starting with molecular characteristics, has been presented by Silveira.⁴

The rotational energy levels of H₂ are given by $E_J = J(J + 1)\hbar^2/2I$. Here J is the angular momentum quantum number (0, 1, 2, ...) and $\hbar^2/2I$ is the rotational constant. The moment

of inertia I is $I = ML^2/4$ from classical mechanics, with L the bond length and M the molecular mass. Because the mass of H₂ is so small (the lightest molecule, in fact) and L is so short (~0.075 nm, the shortest chemical bond) the inertia I is unusually small. Thus the rotational constant $\hbar^2/2I$ is 86 K (multiply by k_B for energy units), unusually large. As shown in Figure 1, the energy levels of the first few states are 0 for $J = 0$, 172 K for $J = 1$, 516 K for $J = 2$, and 1032 K for $J = 3$. Thus, even at room temperature the quantum nature of molecular rotation must be considered. At low temperatures, where the splittings exceed $k_B T$, this is especially important.

Because H₂ has two identical fermions (protons, $I = \frac{1}{2}$), the overall wavefunction ψ must be antisymmetric with respect to proton interchange. The wavefunction is a product of spin (χ) and spatial (ϕ) (i.e. rotational) parts: $\psi = \chi\phi$. The desired antisymmetry under proton interchange can be obtained in two ways (Figure 1). The spin function χ may be symmetric (i.e. total nuclear spin $I = 1$, the parallel arrangement of the proton spins) with the rotational function ϕ antisymmetric (i.e. odd values of quantum number J). This case is *ortho*-H₂. The second possibility is *para*-H₂, which has antiparallel proton spins ($I = 0$) and J restricted to even values.

The distinction between *ortho*-H₂ and *para*-H₂ has profound effects. Most importantly for NMR, only *ortho*-H₂ molecules yield proton NMR signals, since *para*-H₂ has $I = 0$. The specific heats of *ortho*-H₂ and *para*-H₂ in the gas phase are different so they have different thermal conductivities. A simple resistance bridge thermal conductivity analyzer can be used to determine the fraction of *ortho*-H₂ in a mixture.

The equilibrium concentration c of *ortho*-H₂ is 0.75 at and above room temperature. This reflects the multiplicities of the nuclear spin states: $2I + 1$ is 3 for $I = 1$ (*ortho*) and 1 for $I = 0$ (*para*). At lower temperatures the equilibrium concentration falls to 0 at low temperatures, since $J = 0$, is the rotational ground state. At 77 K, for example, the equilibrium $c \simeq 0.50$.

Thus, if H₂ could attain thermal equilibrium at low temperatures, all of the H₂ would be *para*-H₂, $I = 0$, and there would be no NMR signals! However, conversion between *ortho*-H₂ and *para*-H₂ is a very slow process, requiring

Figure 1 Energy level diagram of the H₂ molecule. The rotational energy is $E_J = J(J + 1)\hbar^2/2I$, with $\hbar^2/2I = 86$ K. States are divided into *para*-H₂ (even J , total nuclear spin $I = 0$) and *ortho*-H₂ (odd J , $I = 1$)

days or weeks, depending on the material phase. *Ortho*–*para* conversion is slow because it requires a magnetic field gradient to provide a different field at the two protons, to cause a relative precession of the two spins. Furthermore, the magnetic field gradient must oscillate (or have spectral components) at the frequency corresponding to the 172 K splitting between $J = 1$ and $J = 0$. Thus, static field gradients are ineffective. Paramagnetic materials of high surface area can serve as catalysts to speed the process.

D_2 has two spin-1 deuterons, which are bosons. Thus, the overall wavefunction must be symmetric under interchange of the deuterons. *Para*- D_2 has total nuclear spin $I = 1$ and odd values of J . *Ortho*- D_2 has $I = 0$ or $I = 2$ coupled with even J values. Thus, both *ortho*- D_2 and *para*- D_2 generate deuterium NMR signals. The rotational ground state is $J = 0$; therefore, at low temperatures D_2 becomes increasingly *ortho*- D_2 . The rotational constant $\hbar^2/2I$ is 43 K for D_2 . The high-temperature equilibrium composition is 33.3% *para*- D_2 , as dictated by the spin multiplicities: $2I + 1 = 3$ for *para*- D_2 . For *ortho*- D_2 , there are five states of $I = 2$ and one state of $I = 0$, a total of six spin states. A more sensible naming convention has been suggested: ‘even- J ’ and ‘odd- J ’ are accurate names that self-explain.⁵

For HD, the two nuclei are not identical. There are no interchange symmetry requirements, so no *ortho*–*para* distinction. At low temperatures, HD readily falls into its $J = 0$ ground state. We remark that $J = 0$ HD is a spherically symmetric molecule (!), so the intramolecular dipole interaction between H and D is averaged to zero.

It should be remarked that other molecules (e.g. H_2O , N_2 , and $^{15}N_2$) have *ortho* and *para* species. As their rotational constants ($\hbar^2/2I$) are much smaller, one cannot make the gas cold enough for the equilibrium concentration to deviate substantially from the high-temperature limit. At lower temperatures they solidify and the rotational motion is hindered (librations). The splitting between the lowest librational states of the *ortho* and *para* species is very small in such cases. Thus, the effects of the *ortho*–*para* distinction are by far most prominent with H_2 and D_2 .

Molecular beam measurements⁶ of the molecular energy levels in H_2 , HD, and D_2 have been reported. Thus, the parameters of the nuclear spin Hamiltonian are known to high accuracy. As discussed thoroughly by Abragam,³ there are four terms in the spin Hamiltonian of *ortho*- H_2 . The nuclear Zeeman interaction is the splitting between spin states that results in NMR. There is a molecular Zeeman interaction; this term is relatively unimportant in bulk phases. Even in H_2 gas, collisions occur so frequently that magnetic resonance associated with the molecular Zeeman term is unobservable. The third term is spin–rotation coupling; rotation of the molecule generates a magnetic field at the nuclei. The fourth term is dipole–dipole interaction between the spins. In HD and D_2 , there is an additional, quadrupole interaction between the deuteron(s) and the electric field gradient from the charges in the molecule (see *Quadrupolar Interactions*).

3 SOLID H_2

The contours of constant electronic density of the H_2 molecule are nearly spherical, particularly for the contours at distances of van der Waals contact.⁴ Thus, the angular

Figure 2 Phase diagram of solid H_2 at ambient pressure. The *ortho*- H_2 concentration can be controlled by waiting for the sample to *ortho*–*para* convert partially. Proton NMR lineshapes in the hcp disordered and Pa3 ordered phases are sketched

momentum quantum number J ‘is a good quantum number’ even in liquid and solid H_2 . Although the rotation state is generally an admixture of many eigenstates of different J values, the rotational states in liquid and solid H_2 are nearly pure eigenstates of a single J value. The existence of free-rotor states in the solid does not occur for other systems.

Solid H_2 forms from the liquid at temperatures below 14 K, independent of the *ortho* concentration c , as shown in Figure 2. In the high-temperature, hexagonal close packed (hcp) phase, the proton NMR line (of the *ortho*- H_2) is comparatively narrow.⁷ At temperatures from 14 K down to ≈ 3 K the linewidth is determined primarily by intermolecular dipole interactions. The linewidth is more or less independent of temperature below 10 K; above 10 K the line narrows due to diffusion. The intramolecular interactions (dipole–dipole and spin–rotation) are averaged nearly to zero by rapid transitions among the three m_J sublevels of the $J = 1$ manifold of rotational states. Higher J states are not occupied at such low temperatures (see Figure 1). The rapid Δm_J transitions are analogous to (and are more or less equivalent to) the rapid tumbling of a classical molecule in a fluid. Thus, the hcp phase is ‘orientationally disordered’.

Below the phase transition (Figure 2), an orientationally ordered H_2 structure appears, as studied in the classic paper of Reif and Purcell.² The center of mass lattice is face-centered cubic (fcc), and there are four interpenetrating sublattices (Pa3 crystal symmetry). The *ortho*- H_2 molecules are ‘no longer rotating’, to put it classically. In quantum terms, the energy of one of the three sublevels is lower than the others; this sublevel may be regarded as $J = 1, m = 0$ or, equivalently, the p_z function of orientation. In this state the expectation value of the intramolecular dipole–dipole interaction does not vanish, so the proton NMR line appears as a wide Pake powder doublet, as also discussed by Abragam.³

The dipole splitting in the ordered phase Pa3 is unusually wide, 172 kHz cusp-to-cusp. It is so large because of the very short distance between the protons in H₂. Yet it is interesting to note that the splitting is only $\frac{2}{5}$ the value one would expect from classical formulae for the dipole interaction of fixed protons. The $\frac{2}{5}$ factor is the expectation value of the dipolar $(3 \cos^2 \theta - 1)/2$ term for the p_z wavefunction. That is, in the p_z state, many orientations are present; p_z is not a delta function of orientation. The spin-rotation interaction does not contribute to the linewidth in the ordered phase, because the wavefunction is real and the angular momentum components are quenched: $\langle J_i \rangle = 0$.

It should be noted that Reif and Purcell even measured the dipole interaction strength by zero field NMR, a remarkable feat for the time (see **Zero Field NMR**).

The orientationally disordered phase of H₂ is similar to the rotor (or plastic) crystal phases⁸ of many classical molecules, especially solid N₂ and CO. The high-temperature structures, β -N₂ and β -CO, are rotor solids with the hcp lattice. The low-temperature forms, α -N₂ and α -CO, have the Pa3 crystal structure.⁹ The transition temperatures, 35.6 K for N₂ and 61.5 K for CO, are much higher than for H₂. The parallelism between these systems is intriguing, in light of the quantum mechanical description required for rotation in H₂, while N₂ and CO are well described classically. The only analog to dilution of the *ortho*-H₂ by *para*-H₂ is to form N₂/Ar or N₂/CO/Ar alloys, with argon serving to dilute the molecules.

The orientational ordering of solid H₂ is driven by the electrostatic quadrupole-quadrupole (EQQ) interaction between *ortho*-H₂ molecules. *Para*-H₂ molecules, being $J = 0$ and thus spherical, do not participate in the orientational ordering (they have no orientation). At such temperatures, the *ortho*-H₂ molecules are all $J = 1$ and the *para*-H₂ molecules are $J = 0$. Thus, it is convenient to consider the *ortho*-H₂ as ‘molecular spins-1’; the EQQ coupling is then a molecular spin-molecular spin coupling which induces flip-flops (spin exchanges) between the molecular spins. Thus, spin A may go from $m_J = 1$ to 0 while spin B makes a transition from $m_J = 0$ to 1. In this way, the *ortho*-H₂ molecular spins behave analogously to nuclear spins coupled by magnetic dipole interactions in a solid.

In the high-temperature phase, the nuclear spin T_1 can be calculated using the Bloembergen-Purcell-Pound (BPP) relaxation theory, where the correlation time τ_c describing the intramolecular interactions is the mean time between molecular spin flip-flops: $T_1 \propto \omega_c = \tau_c^{-1}$, because $\omega_0 \tau_c \ll 1$. The rate ω_c of flip-flops, as in the nuclear spin analogy, is independent of temperature and increases with increasing concentration (c) of the *ortho*-H₂ molecular spins. Indeed, this is observed.¹⁰ For $1 > c > \frac{1}{2}$, T_1 varies approximately as $c^{1/2}$; this results from a nearly Gaussian correlation function of the molecular spin quantities (recall that lineshapes in concentrated dipolar solids are nearly Gaussian). For $c \leq 0.3$, T_1 varies nearly as $c^{5/3}$; this result can be rationalized from the (distance)⁻⁵ variation of the EQQ, imagining dilution to occur on a regular sublattice. The statistical theory of dilute-spin lineshapes gives the same results.

When the temperature is decreased to a value roughly equal to the EQQ interaction strength, a first-order transition to the ordered structure occurs. The mean interaction strength involves the pair interaction (about 0.85 K) and the number of nearest *ortho*-H₂ neighbors. Thus, dilution with *para*-H₂

reduces the transition temperature, as in Figure 2. For $c \leq 0.56$, no long range ordered structure appears; this high value of the critical concentration is believed to result from a high degree of frustration of the EQQ interaction. For $c \leq 0.56$ and at low temperatures, a quadrupole glass phase¹¹ appears (see **Ortho-Para Hydrogen at Low Temperature** for a thorough discussion of the quadrupole glass).

Another analog of spin flip-flops is resonant *ortho-para* interchange. In this process, written as $po \rightarrow op$, an *ortho* and a *para* hydrogen interchange. This is not a physical interchange where one molecule moves past the other, but an interchange of the *ortho* and *para* label only. This slow process is driven by a weak term in the intermolecular nuclear spin dipole-dipole interaction between the $I = 1$ *ortho* and the $I = 0$ *para* (the $I = 0$ molecule still has an intermolecular dipole interaction, because the antiparallel proton spins are spatially separated).¹² The effect of the interchanges is to allow *ortho*-H₂ in a dilute sample to cluster together at $T \leq 1$ K. By clustering and properly orienting themselves, they can reduce their energy (by virtue of the EQQ interaction). Horst Meyer, who has contributed so much to the understanding of solid H₂, has reviewed this topic.¹³

Ortho-para conversion is a process which destroys *ortho*-H₂ molecules at low temperatures. In the ordered state (high concentration c of odd- J species at low temperatures), the molecules are all $J = 1$, $m_J = 0$. Because the conversion rate depends on the nuclear spin state m_I , the spin state populations will be driven away from their thermal equilibrium values. For $c \sim 1$ (nearly pure *para*-D₂), a remarkably enhanced deuterium spin signal was observed (by as much as $\times 50$, with some features negative, ‘in emission’).¹⁴ This phenomenon is closely related to the CIDNP effect (see **Chemically Induced Dynamic Nuclear Polarization**). The nuclear spin populations can only be driven away from equilibrium by *ortho-para* conversion in the ordered phase, where T_1 is sufficiently long.

4 H₂ GAS

The nuclear magnetic relaxation of H₂ gas is discussed briefly in the venerable paper¹ of BPP. At ~ 10 atm, it was correctly deduced that H₂ gas was in the limit $\omega_0 \tau_c \ll 1$, explaining why T_1 increased with increasing pressure. It should be remarked that a general familiarity with the ‘pressure broadening’ of infrared absorption lines would lead one to expect the opposite result.

Hardy published the classic study of spin relaxation in H₂ gas at 77 K.¹⁵ The measurements employed extensive signal averaging to improve the signal to noise ratio, long before the digital revolution in signal processing. The work is a beautiful application of the BPP relaxation theory. The correlation time τ_c of the intramolecular spin-spin and spin-rotation interactions is the time between collisions that change the rotational state J , m_J . At 77 K all of the *ortho*-H₂ molecules are confined to $J = 1$, so τ_c refers to the time for m_J to change. Thus, the language of gas phase relaxation is that of molecular scattering. Here, one is interested in scattering events (collisions) that change m_J of one or both molecules. The rate of collisions and hence τ_c are experimentally controlled by varying the density (or pressure) of the gas.

Hardy was able to pass through the T_1 minimum ($\omega_0 \tau_c \approx 1$) by going to sufficiently low densities. In the BPP

theory, the value of the minimum T_1 depends primarily on the strength of the spin–spin and spin–rotation interactions (see *Spin–Rotation Relaxation Theory*), which are known accurately for H_2 from molecular beam studies. The minimum T_1 also depends on the shape of the autocorrelation function (exponential here) and the ratio of correlation times for terms of different multipolar operators. Remarkable agreement between the experimental data and the results of relaxation theory were obtained.

It should be noted that the intramolecular spin interactions in H_2 are unusually large. For example, for relaxation through the dipole–dipole interaction, the relaxation rate T_1^{-1} varies as the square of the interaction strength, R^{-6} . As H_2 has the shortest bond length, it has an unusually rapid spin relaxation rate (Hardy's minimum T_1 at 29 MHz is 200 μs !).

The reader is referred to other articles on NMR in gases (*Gas Phase Studies of Intermolecular Interactions and Relaxation* and *Gases at High Pressure*).

5 DILUTE H_2 IN INERT SOLID MATRICES

H_2 has been studied at low concentrations in liquified¹⁶ and solidified¹⁷ rare gas solids (neon, argon, and krypton). For the solids, the H_2 concentrations ranged from 30 to 2000 ppm (0.2%). The solid solutions were prepared, for example, by bubbling H_2 gas through liquid argon, in a recirculating scheme. The solution was frozen rapidly (several minutes) and the expelled H_2 was then evacuated. Once in solid solution, the H_2 was stable at all temperatures below $\sim 0.8 T_{\text{MELT}}$. The proton NMR data (T_1 and T_2) were independent of the H_2 concentration, suggesting the H_2 molecules were well dispersed. The absence of *ortho*–*para* conversion confirms that the H_2 molecules were not clustered. The H_2 concentration was determined from the proton NMR signal amplitude, in comparison with H_2 gas. With such small concentrations, the 20 MHz proton signals were extensively averaged (up to 100 000 averages); the relatively small value of T_1 (0.5–10 ms) allowed the averaging to be accomplished within a reasonable time.

As a function of temperature, the data for T_1 and T_2 of H_2 in solid neon, argon, and krypton display classic BPP behavior. In argon, for example, there is a T_1 minimum at 13.5 K, with T_2 nearly equal to T_1 above this temperature. Below 13 K, T_2 is much shorter than T_1 . The temperature dependence of T_1 and T_2 is due to a temperature-dependent rate ω_c of Δm_J transitions. Because the data are independent of concentration, the transitions are not driven by the EQQ coupling between the molecular spins (as in solid H_2 , see above). Instead, the transitions are due to phonon–rotation coupling, ‘ T_1 ’ processes of the molecular spins. Such a coupling has also been observed in pure H_2 (dilute in *ortho*- H_2), as well.¹⁸

The minimum value of T_1 in the BPP relaxation theory is determined by the spin interaction strengths and the resonance frequency ω_0 . Thus, it was surprising that the T_1 minimum values in neon, argon, and krypton were nearly equal (0.56 ms), but about four times longer than the minimum T_1 of Hardy's 77 K gas measurements (corrected for the different ω_0 values). In a remarkable paper, Fedders adapted the BPP relaxation theory to the quantum mechanical description of rotational states in *ortho*- H_2 .¹⁹ He postulated a crystal field acting on the H_2 that lifts the degeneracy of the three sublevels.

His calculation makes specific predictions for the minimum T_1 in the case of crystal fields of cubic symmetry (three levels degenerate), axial symmetry (two levels degenerate), and no symmetry (no degeneracies). In brief, various terms in the relaxation Hamiltonian are shifted in frequency by the frequencies separating the $J = 1$ sublevels. Provided the crystal fields are sufficiently strong, the frequency-shifted terms are no longer effective in relaxation. Thus, for splittings much larger than ω_0 , the minimum T_1 values depend only on the symmetry of the crystal fields, and not their strength. In the original paper,¹⁹ the values for the case of no symmetry depend weakly on a parameter R . A technical correction to the angular averaging shows that R is unimportant; the correct values are the ones listed for $R = 0$.¹⁷

Fedders's calculated value for no symmetry agrees to within 10% of the minimum T_1 in neon and argon, and to within 25% for krypton. The crystal field may arise from strains produced from other H_2 impurities. Also, dislocation lines are inevitable in rare gas solids and result in quadrupolar broadening in pure solid krypton (^{83}Kr) and xenon (^{131}Xe), despite their fcc structure (see *Diffusion in Rare Gas Solids*). The dislocations may also produce the crystal fields acting on the H_2 .

Dilute *ortho*- H_2 was also studied in solid *para*- H_2 .¹⁷ The inside of the sample vessel was coated with ferric hydroxide gel, an *ortho*–*para* conversion catalyst. The sample was held in the liquid phase to promote conversion. When the desired concentration of *ortho*- H_2 remained, the sample was frozen; the greatly reduced mobility halted the catalytic conversion. *Para*- H_2 remains in the hcp structure (Figure 2), so an axially symmetric crystal field is expected. A T_1 minimum is observed to occur at the melting point of 14 K; the minimum value (0.30 ms) is in close agreement with Fedders's value for the case of axial symmetry. It is not known why the crystal fields from dislocations and neighboring impurities do not lower the symmetry further, as in the cubic rare gas solids.

Using Fedders's calculations, the observed values of T_1 and T_2 were used to determine the rate ω_c of Δm_J transitions. The behavior of ω_c generally follows a power law, $\omega_c \propto T^n$, with n varying between 2 (high temperature) and ~ 7 (lowest temperatures). This demonstrates that a two-phonon Raman process drives the molecular reorientation. The theory²⁰ of relaxation of quadrupolar nuclei by phonons (two phonons, Raman) can be adapted here, where the ‘molecular spin’ is being relaxed. It was found in all solids (neon, argon, krypton, and *para*- H_2) that an unusually low value of 40 K of the characteristic temperature θ_c of the phonon spectrum (essentially the Debye temperature) was required to fit ω_c as a function of temperature. The origin of the apparently low-frequency modes is not known.

More recently, the behavior of HD in solid argon has been examined with deuteron NMR.²¹ HD has a singlet rotational ground state, $J = 0$, so at low temperatures its T_1 will be relatively long. Above 10 K, the observed relaxation will be due to the few molecules in the first excited states, $J = 1$. At low temperatures, this fraction f is $3e^{-128/T}$, where 128 K is the energy of the three $J = 1$ states. The observed relaxation rate can be divided by this fraction to yield the T_1^{-1} of molecules characterized by $J = 1$. For HD in argon, it appears that transitions among the $J = 1$ sublevels, Δm_J transitions, are responsible for the relaxation, not ΔJ transitions. Using the formalism of Fedders, the T_1^{-1} of $J = 1$ molecules yields the rate ω_c (Γ_2 in the original article)¹⁹ of the Δm_J transitions.

The transition rates ω_c for *ortho*-H₂ and *para*-D₂ at the same temperature in argon differ only by a factor of two, as expected from the masses. But ω_c for HD in argon is larger by a factor of 100! This effect is attributed to the off-center rotation of HD. The electronic cloud of HD, like H₂ and D₂, is nearly spherical and centered on the point ('force center') halfway between the nuclei. But this is not the center of mass, which is closer to the deuteron, away from the proton. For free rotation (about the center of mass), the force center sweeps out a circle of 0.025 nm diameter. In light of this, rotation of HD should generate larger forces and displacements of its neighbors. This is the origin of the enhanced phonon-rotation coupling of HD in argon.

6 H₂ AS A RELAXATION CENTER

The term 'relaxation center' has its origins in paramagnetic species (bearing electronic spins and magnetic moments) which serve to relax the nuclear spins in their vicinity (see *Paramagnetic Relaxation in Solution*).³ But *ortho*-H₂, because of its short bond length, can have a relatively small value of its proton T_1 . By spin diffusion (see *Spin Diffusion in Solids*), the magnetization is propagated to other proton spins in the sample. Thus, *ortho*-H₂ may function as a relaxation center.

6.1 H₂ Relaxation Centers in Solid HD

At temperatures below 4.2 K, HD molecules are confined by the Boltzmann factor to the $J = 0$ state ($J = 1$ is 128 K higher in energy). Since $J = 0$ is a singlet state, no fluctuation or transition between sublevels is possible (compare to $J = 1$ *ortho*-H₂, which has three sublevels). Thus T_1 of pure HD would be expected to be relatively large.

But all HD samples bear some H₂ (and D₂) impurities. For relaxation of the protons in HD, the *ortho*-H₂ content is particularly important. Either through EQQ interaction between $J = 1$ molecules or through coupling of the $J = 1$ 'molecular spins' to phonons, the *ortho*-H₂ will have a mechanism for longitudinal relaxation. Because spin diffusion here is rapid, the overall relaxation rate is then given by spin thermodynamics reasoning as follows:

$$(T_1^{-1})_{\text{overall}} = (T_1^{-1})_{\text{H}_2} \frac{2[\text{ortho-H}_2]}{2[\text{ortho-H}_2] + \frac{3}{4}[\text{HD}]} \quad (1)$$

In equation (1), the factors of 2 and $\frac{3}{4}$ are the values of $I(I + 1)$ for $I = 1$ (*ortho*-H₂) and $I = \frac{1}{2}$ (proton in HD). The square brackets represent number concentrations. Thus, for a known concentration of *ortho*-H₂, the T_1^{-1} of the *ortho*-H₂ molecules themselves may be extracted from the measured, overall T_1^{-1} .

Hardy and Gaines studied the proton T_1 of HD with varying amounts x of H₂ impurity.²² At 4.2 K and $x = 2\%$ they find a broad T_1 minimum as a function of x . This indicates that the correlation time τ_c describing the *ortho*-H₂ rotational states varies with H₂ concentration and passes through the condition $\omega_0 \tau_c \sim 1$. At sufficiently low concentrations, $x < 10^{-3}$, the observed $T_{1\text{overall}} \propto x^{-8/3}$, yielding $(T_1)_{\text{H}_2} \propto x^{-5/3}$. This last

result is just that expected for EQQ interactions among the *ortho*-H₂, given the variation of EQQ as r^{-5} .

The above explanation is not the entire story. For example, there is a temperature dependence of T_1 and a field dependence as well. The result varying as $x^{-8/3}$ only obtains near 4 K, perhaps serendipitously. No complete explanation has appeared for these effects, which have been studied further by others.

Nevertheless, the overall T_1 observed by Hardy and Gaines varied from 0.04 to 10^3 s with H₂ contents from 2×10^{-2} to 10^{-4} . That T_1 is still changing at $x = 10^{-4}$ is a clear demonstration of the role of *ortho*-H₂ molecules as relaxation centers for the HD protons in this solid.

6.2 H₂ Relaxation Centers in Amorphous Silicon

Amorphous silicon (see *Amorphous Silicon Alloys*) is commonly formed from a plasma or glow discharge containing silicon and hydrogen atoms (from SiH₄ with added H₂). The solid that forms has hydrogen atoms covalently bonded to silicon, with the silicons forming a covalent, noncrystalline network. The hydrogen atoms are crucial for this semiconductor, tying up dangling bonds that result for non-fourfold-coordinated silicon atoms. Typical material has ~ 10 at% hydrogen. The hydrogen atoms are dipolar coupled to each other, with separate broad (more clustered) and narrow (less clustered) components in the proton NMR line.

A pronounced T_1 minimum was observed as a function of temperature near 30 K for the protons in amorphous silicon. Given the covalent nature of the structure, atomic motions at $\sim 10^8$ s⁻¹ are completely unexpected at such low temperatures. Two-level tunneling systems were suspected. However, a small fraction of the protons being involved in fairly small atomic displacements (the usual picture of the tunneling systems) is incompatible with the rapid relaxation observed ($T_1 \sim 0.25$ s near 30 K).

It was proposed that a small fraction of the hydrogen atoms form H₂ molecules which serve as relaxation centers.²³ The model assumed (see below) that the H₂ were dilute, as in the study of H₂ in inert solids (above). The correlation rate ω_c of the *ortho*-H₂ molecules was assumed to arise from phonons (being dilute, EQQ interactions should be negligible). Thus, the model predicted a temperature-dependent relaxation rate T_1^{-1} of the *ortho*-H₂. The overall relaxation rate in the limit of rapid spin diffusion would be given by an equation similar to equation (1), with the protons covalently bonded to silicon in place of the HD protons. To account for finite spin diffusion, the above estimate must be modified:

$$(T_1)_{\text{overall}} = T_{\text{spin diffusion}} + (T_1)_{\text{H}_2} \frac{2[\text{ortho-H}_2] + \frac{3}{4}[\text{H}]}{2[\text{ortho-H}_2]} \quad (2)$$

In equation (2), the right-hand term is the reciprocal of the overall T_1^{-1} from equation (1) (that is, $T_{1\text{overall}}$); the two terms are added as times because they are sequential processes, as shown in Figure 3.

With approximately 1% of the hydrogen atoms present as H₂ molecules, the model accurately describes the data. The value of $T_{\text{spindiffusion}}$ in equation (2) is in reasonable accord with calculations based on the assumed concentration of H₂. In fact, the spin diffusion bottleneck is crucial, because it explains

Figure 3 Relaxation of hydrogen atoms covalently bonded to silicon proceeds through two sequential steps. First, spin diffusion transports magnetization to and from the *ortho*-H₂ relaxation centers. Second, the *ortho*-H₂ relax to the lattice through phonon-induced transitions among the three sublevels of $J = 1$

the absence of a strong ($\sim \omega_0$) frequency dependence of the minimum value of T_1 . Instead, the minimum T_1 is controlled by spin diffusion.

The ultimate test of the above model was performed by Carlos and Taylor.²⁴ Over a period of 3 months, an amorphous silicon sample was held at 4.2 K. Occasionally the sample was removed and its proton T_1 measured at temperatures near 30 K. The T_1 minimum remained at 30 K, but the minimum value of T_1 increased from 0.25 to 3.5 s as the H₂ relaxation centers *ortho*-*para* converted. Both terms in equation (2) are expected to increase as the *ortho*-H₂ becomes dilute through conversion. The minimum value of T_1 decreased rapidly during a 300 K ‘anneal’, showing reconversion of *para*-H₂ to *ortho*-H₂.

The observation of an *ortho*-*para* conversion rate in reasonable agreement with that in bulk solid H₂ suggests that the H₂ molecules are clustered. However, the dipole coupling between a covalently bonded hydrogen atom and an H₂ molecule would also result in *ortho*-*para* conversion, in the case of dispersed H₂. There is additional evidence of clustering from later work. If the H₂ molecules are in fact clustered, why is their τ_c determined by phonon-induced transitions instead of EQQ-driven flip-flops? If clustered, the EQQ-driven flip-flops must be quenched by different and strong crystal fields at neighboring molecules (similar to the quenching of nuclear spin diffusion near a paramagnetic impurity).

The observation of the effects of *ortho*-*para* conversion and reconversion on the proton T_1 is conclusive evidence of the role of H₂ as a relaxation center in amorphous silicon. At the time, there was no other evidence of H₂ in this material, nor was there acceptance of the notion.

6.3 H₂ Relaxation Centers from Metal Hydrides

Many metals are capable of absorbing large amounts of hydrogen (see *Hydrogen–Metal Systems*). The hydrogen dissociates and occurs as individual protons at interstitial sites in the metal lattice. The principal mechanisms of proton spin relaxation are through hydrogen diffusion and the Korringa mechanism.²⁵ But in many metal hydrides there is an additional and strong relaxation mechanism that appears at high temperatures (typically above 1273 K). The identity of the anomalous relaxation has been a lively issue.

In one hydrogen–metal system, Nb_{0.5}V_{0.5}H_{0.36}, it has been demonstrated that the anomalous relaxation is due to the diffusion of hydrogen to the surface of the small metal particles (necessarily small to allow penetration of the rf fields), surface

recombination to yield H₂ gas, and rapid relaxation of H₂ in the gas.²⁶ This seems remarkable because the density of protons in the gas phase is only $\sim 1\%$ of that in the metal host. At typical temperatures, the H₂ vapor pressure is a few atmospheres.

The most conclusive experiments on the anomalous relaxation were conducted with argon gas overpressures applied to the metal hydride. Argon pressures of only ~ 30 atm served to reduce the anomalous relaxation rate by a factor of 4; such a large effect could not possibly arise from the minuscule compression of the metal hydride solid itself. Instead, the increase in T_1 is due to the increased rate of scattering of *ortho*-H₂ molecules upon addition of argon to the gas phase surrounding the particles. A simple model yields a good fit to the variation of T_1 with argon overpressure, the change in proton T_1 upon 90% deuterium substitution, and the temperature dependence of the anomalous relaxation.

Because of its large spin interactions, the H₂ molecule functions as a relaxation center in the gas phase. At these high temperatures, physical diffusion and surface exchange rapidly transport the magnetization through the solid.

7 MULTIPLE ECHOES

The deuteron spin in HD has an electric quadrupole interaction with the charges in the molecule and a magnetic dipole interaction with the proton spin. These interactions have the same angular dependence. An important result is that any molecular motion will have the same averaging effect on the two interactions, so their ratio will be unchanged.

The quadrupole interaction splits the Zeeman lines, resulting in a symmetric spectrum with lines at $\omega_0 \pm \omega_Q$. The dipole interaction with the proton (assumed to be up) shifts these lines by ω_D , resulting in a two-line spectrum at $\omega_0 \pm \omega_Q + \omega_D$. A different HD molecule with its proton down generates two lines at $\omega_0 \pm \omega_Q - \omega_D$. So, a sample of HD (at least partially oriented so ω_Q and ω_D are not averaged to zero) contains four lines—a double doublet. The overall spectrum is symmetric about ω_0 , though this is not so for the spectra of individual molecules. In a powder, the spectrum will be a pair of Pake doublets; the ratio of their splittings will be $(\omega_Q + \omega_D)/(\omega_Q - \omega_D)$, outer doublet to inner doublet. For HD, where the interactions are known accurately from molecular beam work, this ratio is 1.72.

Consider the response of a deuteron in HD (with proton up) to a two-pulse sequence (Figure 4). A component of the spin coherence will dephase after the first pulse by running at the lower transition frequency ($\omega_0 - \omega_Q + \omega_D$); we will consider the portion at the upper frequency later. The second pulse has two effects. Part of the coherence is phase inverted and continues to run at the lower frequency, forming an echo at 2τ . Part of the coherence is moved to the higher-frequency transition ($\omega_0 + \omega_Q + \omega_D$), so that it rephases faster ($\omega_Q + \omega_D$) than it dephased ($|\omega_0 - \omega_Q + \omega_D| = \omega_Q - \omega_D$, as $\omega_D < \omega_Q$ here). This part of the coherence is refocused at a time t^* after the second pulse: $t^* = \tau(\omega_Q - \omega_D)/(\omega_Q + \omega_D)$. That is, this echo is early! Similar consideration of the coherence starting at $\omega_0 + \omega_Q + \omega_D$ and ending at $\omega_0 - \omega_Q + \omega_D$ (rephases slower than it dephased) leads to a late echo, at $t^* = \tau(\omega_Q + \omega_D)/(\omega_Q - \omega_D)$.²⁷ Similar treatment of the case with proton down yields the same times of echo formation. The above reasoning can easily be framed in terms of the density matrix; these echoes

Figure 4 Sketch of deuteron multiple echoes from HD molecules, in response to a pair of rf pulses. The cases *xx* and *xy* refer to the rf phases of the pulses

are similar to the multiple echoes observed by Solomon²⁸ in a purely quadrupolar case.

Thus, echoes are expected as shown in Figure 4 at the usual times 2τ , 1.58τ , and 2.72τ (here $0.58 = 1/1.72$). The echoes are observed in an amorphous silicon sample²⁷ with HD and for HD adsorbed on MgO²⁹ at 1.56τ , τ , and 2.78τ , in good agreement. Presumably, the molecular parameters leading to ω_Q and ω_D are slightly perturbed in the solid state.

In *para*-D₂ with total nuclear spin $I = 1$, only the 2τ echo is predicted and observed. But *ortho*-D₂ (even J and $I = 0$ and 2) yields three echoes, just like HD. The correct treatment of the problem requires the energies of the six spin states and the transition frequencies to be calculated. There are two states of $m_I = 0$, which are linear combinations of $I = 0$ and $I = 2$, $m_I = 0$. In other words, I is not a good quantum number in *ortho*-D₂. Multiple echoes are predicted at the times 1.86τ , 2τ , and 2.17τ , in good agreement with observations in deuterated amorphous silicon²⁷ and with D₂ adsorbed on MgO (see below).²⁹ The early and late echoes are closer to the 2τ echo, because the dipole interaction is smaller in D₂ than in HD.

The behavior of the echoes with respect to the phases of the rf pulses is sketched in Figure 4 and agrees with a calculation invoking the density matrix. By adding or subtracting the echoes from *xx* and *xy* pulse sequences, one can obtain just the early and late echoes or just the 2τ echo.

The explanation of the multiple echoes is so natural that one may wonder why multiple echoes are not commonly observed in other systems. Quadrupole and dipole interactions are required, with identical angular dependences. Furthermore, neither interaction can be overwhelmingly larger than the other, because this will lead to the three echoes all occurring very near 2τ . A likely candidate is a deuteron bonded to a ¹³C in an organic molecule. Still, the dipole interaction will be much smaller than in HD or even D₂, so the extra echoes will occur quite near the 2τ echo.

8 PHYSISORBED HYDROGEN

Here, two-dimensional (2D) H₂ films are discussed. The H₂ (or HD or D₂) has been adsorbed (see *Adsorbed Species: Spectroscopy and Dynamics*) by van der Waals forces onto a smooth, clean, uniform substrate. In order to obtain observable

signal intensities, the substrate cannot be a cleaved single crystal, but is a high-area powder which, nevertheless, has surfaces that are smooth on the atomic scale. The emphasis of the work discussed is on 2D phases and phase transitions. This is in contrast to work which emphasizes molecular orientation on the substrate and is aimed at understanding surface chemistry (see *Supported Metal Catalysts*).

8.1 H₂ and D₂ Adsorbed on Graphite

The goal of this work was to study the orientational ordering phase transition (see Figure 2) in 2D. At the coverages employed by Kubik, Hardy, and Glattli,³⁰ the H₂ forms a commensurate (registered, epitaxial) monolayer above the graphite basal plane. Because the critical concentration for long-range orientational ordering is large even in 3D (see Figure 2), H₂ and D₂ enriched in the $J = 1$ species were used. That is, the $J = 1$ concentration was increased to nearly 100%, much larger than the 75 and 33% high-temperature limiting values for H₂ and D₂ in thermal equilibrium, respectively.

There are two important anisotropic interactions acting on the H₂ molecules. First, the crystal field from the substrate may tend to align the molecular axis perpendicular or parallel to the surface. For the symmetry of a graphite surface and at the registered sites, the crystal field is expected to be axially symmetric. This will split one of the degeneracies of the three $J = 1$ sublevels, leaving two states degenerate. The other important interaction is the coupling from one molecule to the next, which should be predominantly EQQ. The molecular orientations result from the interplay of the two interactions. This can be understood by regarding H₂ as a classical rotor characterized by $J = 1$. For example, if the crystal field is large and establishes an orientation of the H₂ perpendicular relative to the surface, there is no degeneracy for the EQQ interactions to lift, and no ordering phase transition. For a large crystal field preferring the H₂ molecules to lie in the substrate plane, the coupling between the molecules will split the degenerate (planar) orientations, with a phase transition to the herringbone structure.

NMR experiments on such samples are carried out in a continuous wave mode to avoid heating of the somewhat conductive Grafoil substrate. Because the samples *ortho-para* convert and because the enriched $J = 1$ samples are difficult to make, the experiments are quite difficult.

Near 0.6 K, H₂ with $c = 0.9$ undergoes a sharp phase transition. The orientations of the molecules on the substrate were determined by using oriented stacks of Grafoil, thus avoiding a powder average. With the magnetic field perpendicular to the Grafoil planes, there are peaks in the proton NMR corresponding to molecules perpendicular to the field (i.e. in the plane) and molecules parallel to the field (normal to the plane). The relative intensities agree with the pinwheel structure. Surprisingly, D₂ with high $J = 1$ concentration did not display an orientational ordering transition. It is not understood why the isotopes should behave so differently.

8.2 HD Adsorbed on MgO

MgO can be prepared from magnesium ribbon to yield cubes of ~ 40 nm per side with atomic smoothness. This substrate

is preferable to graphite/Grafoil for NMR, because it is not magnetic and because it is not conductive. MgO can have almost as large a specific area as Grafoil ($\sim 25 \text{ m}^2 \text{ g}^{-1}$).

For coverages $x \leq 0.85$ ($x = 1$ is a compressed monolayer) and $T \approx 5 \text{ K}$, the deuteron resonance of HD on MgO^{29} displays a pair of Pake doublets—a double doublet. This is due to the combination of the deuteron quadrupole interaction and the proton–deuteron intramolecular dipole coupling (see above); the ratio of the splittings is 1.78, as expected. At these two temperatures, HD is in its rotational ground state ($E = 128 \text{ K}$ for $J = 1$). If this were a pure $J = 0$ (spherical) state, the quadrupole and dipole couplings would be zero. The existence of the doublets then demonstrates that the rotational ground state has a substantial admixture of higher J states, resulting from the strong crystal field of the ionic substrate. By comparison, the crystal fields acting on $J = 1 \text{ H}_2$ and D_2 on graphite are only $\sim 2 \text{ K}$.³⁰

The splitting value indicates that $\bar{P}_2 = \langle \frac{3}{2} \cos^2 \theta - \frac{1}{2} \rangle = 0.15$ for HD on MgO. This may be compared with $P_2 = 0$ for $J = 0$ and $P_2 = 0.4$ for $J = 1$, $m = 0$. Thus, there are large numbers of higher J states for HD on MgO, implying strong crystal fields ($\sim 50 \text{ K}$). Importantly, the crystal field will be different at different sites, as will the splitting.

For $x \leq 0.60$ and $T \approx 5 \text{ K}$, the splittings are essentially constant, with a single set of double doublets. This demonstrates that all molecules occupy equivalent substrate sites (commensurate structure) in an island growth regime. The structure is $c(2 \times 2)$, and the area per molecule agrees with the limiting coverage of 0.60. Motional averaging is ruled out by the unchanged spectrum down to 1.8 K at $x = 0.48$.

For $0.60 < x \leq 0.85$, the spectrum is still a single set of double doublets, but with splittings that decrease $\sim 20\%$ from $x = 0.60$ to $x = 0.85$. Together, these imply motional averaging over inequivalent sites. This is remarkable at the temperatures ($4\text{--}6 \text{ K}$) of the observations. The decrease in splitting with increasing coverage reflects an increasing fraction of sites with smaller crystal fields. This explanation (motional averaging) is confirmed by broadening of the lines at reduced temperatures. For example, at $x = 0.73$, broadening is evident already by 4.2 K . For $0.9 \leq x \leq 1.0$, the deuteron NMR line is broad and featureless. Evidently, a broad distribution of sites results in a distribution of splittings. Whatever avenue of motion and motional averaging is available for lower coverages is blocked at these higher densities. The analogy of a filled parking garage may be relevant.

Coverages greater than $x = 1$ yield multilayers. For example, $x = 1.5$ corresponds to a full monolayer, with half of it covered by a second layer. The deuteron NMR spectrum of the first layer is broad and featureless, as found for $0.9 \leq x \leq 1.0$. The signal of the second layer, however, is a sharp, single line. Second layer HD molecules are far from the MgO and feel a much weaker crystal field, so their rotational state is nearly pure $J = 0$; a sharp NMR line is the result. Thus, deuteron NMR allows an unambiguous separation of first-layer and second-layer molecules.

A sample of $x = 0.5 \text{ HD}$ plus $x = 1.0 \text{ H}_2$ was mixed, adsorbed, annealed at 40 K , and recooled. The deuteron NMR (only from HD) consisted only of a broad line. This proves that all of the HD was in the first layer, with the H_2 in both layers. A sample of $x = 0.4 \text{ HD}$ plus $x = 1.1 \text{ D}_2$ was similarly prepared. The deuteron NMR signal here comes from both species, so they are harder to distinguish. But multiple echoes

(see above) are observed only from first-layer molecules, because of the long T^*_2 of the second layer. For this mixture, the multiple echoes occurred only at the times appropriate for *ortho*- D_2 , and not for the times appropriate for HD. Thus, all of the first-layer molecules are D_2 .

These remarkably complete isotope separations are believed to result from zero-point motion effects. The binding of a hydrogen molecule to a substrate will decrease in the order D_2 , HD, H_2 , the order of increasing vibrational frequency above the substrate and increasing zero-point motion. Thus, the more massive molecules will be found in the first layer and the less massive in the second layer, to the extent permitted by the starting composition.

1 INTRODUCTION TO NMR OF HYDROGEN–METAL SYSTEMS

The exposure of hydrogen to metals often produces significant changes in the physical properties of those metals. The absorption of hydrogen into interstitial lattice sites between metal atoms causes metallic materials to expand their volume, changes the crystal structure, and may change the electronic structure or electrical character of the material. Unable to withstand the strain, some metals fracture into powder, sometimes a useful method of producing powder of ductile metals, but at other times a possibly disastrous result as in the case of hydrogen embrittlement of steels. All the materials included in hydrogen–metal systems (HMSs) are occasionally incorrectly referred to as metal hydrides. As we will see below, metal hydrides do make up the majority of materials in HMSs. Metal hydrides can be either covalent, ionic, or metallic¹ in nature. We will confine our attention to metallic hydride materials.

One of the earliest NMR studies of hydrogen in metals was done some 40 years ago by R. E. Norberg,² who applied hydrogen to the palladium metal wires which made up the rf coil of his NMR probe. Linewidth, Knight shift, and relaxation times of the hydrogen in the rf skin depth of the palladium wires were studied by continuous wave and spin echo techniques.

Some of the most basic NMR studies of HMSs have been the investigation of the underlying physical principles governing hydrogen location and motion at the atomic or ‘microscopic’ level. Long-range hopping or diffusion of hydrogen is currently understood in terms of thermally activated, over the barrier hopping between interstitial lattice sites, which will be discussed, in part, below. Pulse magnetic field gradient NMR to measure hydrogen (and other atomic) diffusivities is discussed elsewhere (see *Diffusion in Solids*). Attempts to characterize tunneling of hydrogen at low temperatures between interstitial vacancies in metals at low temperatures by NMR will be discussed briefly here.

Although NMR is a powerful tool for observing hydrogen interactions in HMSs, interpretation of NMR data cannot be

done properly without other knowledge of the materials. Crystal structure and phase diagram results from X-ray, neutron diffraction,³ and detailed magnetic information from susceptibility measurements are often crucial to the interpretation of NMR results of HMS.

Many of the applied NMR studies of hydrogen, deuterium, and tritium in HMSs have been undertaken to determine the location and motions of hydrogen within the metallic materials in efforts to characterize and improve the hydrogen–metal materials for applications such as purification of hydrogen, hydrogen isotope separation, and hydrogen storage for fuel or energy storage (batteries); or closed cycle, metal hydride refrigerators for remote or applications to vehicles in space.⁴

HMSs include elemental metals, MH_x , with small concentrations of hydrogen, e.g. $x < 0.01$, dissolved in the host material with hydrogen located in interstitial vacancies without significant change in the crystal structure of the metal host, M . These materials are referred to as hydrogen (metal) solid solution (α) phases. The solubility of hydrogen in metal solid solutions often diminishes rapidly with decreasing temperature, forming metal hydride precipitates at lower temperatures. High hydrogen concentrations, $x = H/M$, often extend to $x = 3$ or 4 for metal hydrides, e.g. LaH_3 , SnH_4 , and PbH_4 , where the crystal structure of the hydride (β or γ) phase, e.g. face centered cubic (fcc) (or CaF_2 structure) for YH_2 , is usually quite different from the parent metal, e.g. hexagonal close packed (hcp) for Y , and the density of the metal hydride typically is less than the parent metal density. Intermediate hydrogen concentration samples may be mixed hydrogen–metal solid solution α and metal hydride β phases. The observed NMR spectra and nuclear spin–lattice, R_1 , and spin–spin, R_2 , relaxation rates as functions of temperature may give evidence of the mixed phases (see *Phase Transitions and Critical Phenomena in Solids*).

HMSs include hydrogen solid solutions of elemental metals, binary metal alloys, and intermetallic compounds, and also hydrides of metals, alloys, and intermetallic compounds. In addition, metallic halide compounds⁵ and metal sulfides⁶ adsorb hydrogen to significant degrees and should be included in HMSs. Some alloys and intermetallic compounds do not survive the hydriding process, but will disproportionate into hydrides of one or more of the metals and other compounds. In these cases, the hydride of the constituent metal is more stable than the hydride of the parent material.

Most NMR hydrogen–metal studies are made with samples sealed in quartz tubes to prevent loss of hydrogen upon heating the samples and to prevent oxidation or other contamination. Generally, the metallic nature of the materials requires powdered samples (particle size $\leq 100 \mu m$) to permit the B_1 rf magnetic field to penetrate the metallic particle’s ‘rf skin depth’ uniformly. The spaces between powder particles contain hydrogen gas molecules which represent a characteristic hydrogen over pressure of the particles typical for that material, nominal hydrogen concentration, and sample temperature. The hydrogen gas molecules between particles are in constant exchange with the hydrogen atoms or ions within the metallic particles. The hydrogen exchange rate is often quite low for room temperature, but may be many orders of magnitude greater for $T > 700 K$.

The density of the hydrogen inside some hydrogen storage materials, e.g. $LaNi_5H_6$, is greater than the hydrogen density in liquid hydrogen by a factor of two or three. Generally, the

hydrogen density in the metallic powders is many orders of magnitude greater than the density of gas molecules between powder particles. Thus, the observed hydrogen spectrum is typically the spectrum of the hydrogen in the metal only. Recently, anomalously high proton spin–lattice relaxation rates, R_1 , observed for $T > 700$ K within the metal particles⁷ have been understood in terms of exchange between bulk hydrogen atoms in the metallic powder and the much faster relaxing hydrogen gas molecules between the metallic powder particles⁸ (see *Hydrogen Molecules*).

2 HYDROGEN MOTION IN METALS DETECTED BY NMR

The early measurements of Norberg² demonstrated the motion of hydrogen in palladium. HMSs have been studied by NMR beginning with wideline CW methods measuring rigid lattice or low temperature linewidths and lineshapes. The low temperature or rigid lattice hydrogen linewidth originates from the magnetic interactions of the nuclear dipoles in the solid HMSs. Narrowing of the spectral lines with increasing temperatures gave clear evidence of hydrogen motion or hopping into interstitial vacancies within the solid.⁹ This rapid hopping of hydrogen results in a simple averaging of the local magnetic field B_L or the distribution of magnetic fields ‘seen’ by the hopping proton magnetic dipole moment. These motional narrowing studies yielded activation E_a energies of diffusion and moderately precise estimates of hydrogen jump frequencies, $\nu_j(T)$, or alternately, of hydrogen ‘dwell times’ or mean residence time, $\tau_D(T) = 1/\nu_j(T)$, and hydrogen correlation times, $\tau_c(T)$. With increasing T , when the average hydrogen jump frequencies exceeded the rigid lattice linewidth, the observed spectral lines narrowed. The temperature range for line-narrowing measurements was generally less than 100 K; Figure 1 from Schreiber and Cotts¹⁰ shows multiple line-narrowing graphs of LaH_{2+x} against

temperature. Lanthanum hydride shows the unusual ability to absorb hydrogen between compositions LaH_2 and LaH_3 , maintains an fcc structure, and with each additional hydrogen, every hydrogen atom jumps more rapidly. In most HMSs, with increasing temperature, the average hydrogen jump frequency can easily exceed the proton resonance frequency.

The proton linewidths versus temperature¹¹ in zirconium chloride hemihydride ($\text{ZrClH}_{0.5}$) and zirconium chloride monohydride (ZrClH) are shown in Figure 2. This transition metal halide structure consists of two zirconium metal layers sandwiched between two chlorine layers. Hydrogen is known to reside in interstitial tetrahedral sites between the two zirconium metal layers. In addition, the crystal structures for the hemi- and monohydrides are known to be slightly different, due to the presence of the hydrogen in the material.¹²

Indirect evidence of hydrogen (deuterium) hopping was also observed on studying the ^{93}Nb electric quadrupole perturbed, NMR satellite line narrowing in $\text{NbH}_{0.73}$ and $\text{NbD}_{0.82}$ with increasing temperature.¹³ Figure 3 shows the narrowing of the inhomogeneously broadened ^{93}Nb NMR satellite linewidth. This narrowing can be understood in terms of reducing the randomness (inhomogeneity) of the average value at the niobium ion sites due to the increased rapidity of the hopping motion of the hydrogen (deuterium) ions with temperature and their associated electrical charges in the vicinity of the niobium ion sites. The reduced average EFG at the ^{93}Nb site yielded a narrower NMR satellite linewidth. Thus, the stationary niobium NMR showed evidence of the mobile hydrogen (deuteron) ions hopping.

3 DYNAMIC STUDIES OF HYDROGEN MOTION IN A METAL

The magnetic dipole interactions of hydrogen with other hydrogen magnetic moments, with the host metal nuclear

Figure 1 Proton linewidths ($1\text{G} = 10^{-4}\text{ T}$) plotted against T for different x values. (Reproduced by permission of the American Physical Society from Schreiber and Cotts¹⁰)

Figure 2 Temperature dependence of the proton linewidth in the two hydride phases of ZrCl, measured at nominal resonance frequency of 26 MHz. (Reproduced by permission of Elsevier Science Publishers B.V. from Hwang et al.¹¹)

moments, paramagnetic impurity moments, and with conduction electron magnetic moments generally govern the flow of spin energy within HMSs. Cross relaxation of protons and host metal nuclei having large nuclear electric quadrupole interactions has been observed. Also, as shown below, the hopping deuteron can be relaxed by interactions of its electric quadrupole moment with fluctuating EFGs within the material.

The observed hydrogen spin-lattice relaxation rate $R_1(\omega, T)$ varies greatly with temperature in HMSs, and is often the sum of several independent $R_1(T)$ rates, each due to separate physical relaxation mechanisms active in the material. Fortunately, these several R_1 rates have different resonance frequency and/or temperature dependences. With this fact in mind, we shall see how one can separate these spin-lattice relaxation mechanisms and thereby begin to characterize the materials.

The observed hydrogen spin-lattice relaxation rate (HSLR) R_1 , in general, may be the sum of several of the following rates:¹⁴

$$R_1 = R_{1d} + R_{1e} + R_{1p} + R_{1CR} \quad (1)$$

where R_{1d} is the magnetic dipole-dipole relaxation of the hydrogen due to other hopping hydrogen. Bloembergen, Purcell and Pound¹⁵ (BPP) were first to suggest the form of relaxation

$$R_{1d} = \frac{1}{T_{1d}} = M_2(T)J(\omega_0, T) \quad (2)$$

where M_2 is a mean-square fluctuating field most commonly thought to be related to the magnetic dipole-dipole interaction of the hydrogen with other magnetic moments. However, in the case of the deuteron, this formalism can also be

Figure 3 Wide line absorption derivative spectra of ^{93}Nb for 300 and 386 K. At 386 K hydrogen jumping rates are sufficiently fast to produce a spatial average of the electric field gradient at the Nb metal sites which narrows the spectra. (Reproduced by permission of Elsevier Science, Inc., from Hwang et al.¹³)

expressed in terms of the fluctuations of the EFG about the deuteron electric quadrupole moment.¹⁶ In this case, R_{1d} is then written R_{1q} (q denoting quadrupolar relaxation). ω_0 is the spin precession frequency in angular frequency units. $J(\omega_0)$ is the power spectrum or spectral density function of the fluctuation magnetic fields (or fluctuating EFGs) within the sample. The simplest form of $J(\omega)$ is the Lorentzian

$$J(\omega) = \frac{\tau_c}{1 + \omega^2\tau_c^2} \quad (3)$$

where τ_c is the correlation time and is strongly temperature dependent. Often τ_c varies exponentially with temperature, where $\tau_c = \tau_0 \exp(-E_a/kT)$ and where $1/\tau_0$ is thought to be the attempt frequency of hydrogen jumping or the high temperature 'rattling' frequency of hydrogen within the interstitial site.

Equation (2) is often written with an additional Lorentzian term, including dipolar interaction terms at 2ω , as

$$R_{1d} = M_2(T) \left(\frac{\tau_c}{1 + \omega^2\tau_c^2} + \frac{4\tau_c}{1 + (4\omega^2\tau_c^2)} \right) \quad (4)$$

This simple description includes no details of the hydrogen interactions with metal nuclear moments or structure considerations of the HMS. It also ignores any orientation dependence of the crystal (sample) with the magnetic field $\mathbf{B}_0$ direction. Nonetheless, this BPP description is quite a good characterization of the hydrogen relaxation in many simple HMSs.

In a detailed description of hydrogen relaxation anisotropy in single crystal HMSs, Hoke et al.¹⁷ gave the relaxation rate

of protons in an hcp single crystal of $\text{ScH}_{0.25}$ as

$$R_1 = \left(\frac{\mu_0}{4\pi}\right)^2 \gamma_H^2 \gamma_S^2 \left(\frac{h}{2\pi}\right)^2 S(S+1) \left(\frac{1}{12} J^{(0)}(\omega_H - \omega_S) + \frac{3}{2} J^{(1)}(\omega_H) + \frac{3}{4} J^{(2)}(\omega_H + \omega_S)\right) \quad (5)$$

following Abragam¹⁸ where γ_H and γ_S are the gyromagnetic ratios of the hydrogen and metal, S is the spin (in this case, ^{45}Sc $S = \frac{7}{2}$), and $J^{(q)}(\omega)$ are spectral density functions which depend on the diffusion model chosen and on the orientation of the crystal in the magnetic field. Within the three spectral density functions $J^{(0)}$, $J^{(1)}$, and $J^{(2)}$ the frequencies $\omega_H - \omega_S$, ω_H , and $\omega_H + \omega_S$ are the difference between hydrogen and metal frequencies, the hydrogen frequency, and the sum of hydrogen and metal frequencies, respectively.

Interestingly, the anisotropy in R_1 originates in the anisotropy of $J^{(q)}(\omega)$, written by Sholl¹⁹ as

$$J_{qq'} = \sum_{\alpha, \beta} \frac{Y_{2q}(\Omega_\alpha)}{r_\beta^3} \frac{Y_{2q'}(\Omega_\beta)}{r_\beta^3} P(r_\alpha, r_\beta, \omega) \quad (6)$$

where Y_{2q} are spherical harmonics, r_α is the distance between the proton and metal spin at time zero, and r_β is the distance between the proton and metal spin at time t . $P(r_\alpha, r_\beta)$ is the Fourier transform of the probability function for the diffusion model chosen.¹⁷

The conduction electron moments in the HMS relax the hydrogen moment through a contact hyperfine interaction the same as is associated with the Knight shift.^{18,20} The relaxation rate R_{1e} is proportional to the temperature and the square of the Knight shift (see Section 4 for a simple description of the Knight shift) and the square of the density of unpaired electronic (moment) states at the Fermi energy $N(E_F)$. Generally, the better the conductivity of the metallic material the greater the electronic relaxation rate R_{1e} :

$$R_{1e} = \frac{1}{T_{1e}} \propto N^2(E_F)T \quad (7)$$

For a simple metallic material, combining the Knight shift with relaxation rate,

$$T_{1e} T K^2 = \frac{T}{R_{1e}} K^2 = \frac{h/2\pi \gamma_e^2}{4\pi k \gamma_n^2} \quad (8)$$

where γ_e and γ_n are the electron and nuclear (hydrogen) gyromagnetic ratios. This equation is known as the Korringa or Heitler-Teller-Korringa (HTK) relation,²¹ where the Knight shift and R_{1e}/T are theoretically constant in temperature and R_{1e}/T or $1/T_{1e}T$ is often used to characterize the electronic relaxation in HMSs.

Unwanted paramagnetic ion concentrations, ignored in several NMR studies of HMSs, have shown unusual, anomalous relaxation rates and 'extra features' in the measured HSLR which have been attributed to a fictitious complex or additional diffusion mechanism. Phua et al.²² showed that many such unusual or extra relaxation mechanisms were most likely due to the existence of residual paramagnetic impurities (dirt) in the host metals present at the time of the formation of the HMS. That study showed, generally, that the extra spin-lattice

Figure 4 Proton spin-lattice relaxation time T_1 vs. $1000/T$ in YH_2 vs. Gd impurity concentration. (Reproduced by permission of American Physical Society from Phua et al.²²)

relaxation rates, R_{1p} , were linearly proportional to the concentration of paramagnetic impurities present. In addition, extra minima in $\log(T_1)$ versus $1/T$ were a direct result of the impurity relaxation; see Figure 4 for evidence of the suppression of $\log(T_1)$ versus $1/T$ and 'extra minima'. The paramagnetic moments produce a relaxation rate R_{1p} in HMS and can relax hydrogen by spin diffusion at low temperature in the low hydrogen diffusion regime. At higher temperatures, in the fast diffusion regime, hydrogens approach the stationary paramagnetic ions by rapid hopping within the sample and are relaxed via direct dipolar interactions with the paramagnetic impurity ions.

The cross relaxation of the proton, R_{1cr} , with certain host metal nuclei which have large electric quadrupole moments and subsequently large quadrupole interactions was recognized for protons in HMS at low temperatures (see Figure 5) where hydrogen hopping rates are slow. The strong nuclear electric quadrupole interactions of the metal nuclei, e.g. ^{175}Lu in $\text{LuH}_{0.20}$ ²³ and ^{181}Ta in Ta_2H ²⁴ are many tens of megahertz in extent (width) and are only perturbed by the static magnetic field B_0 required for proton resonance. Although the ^{93}Nb quadrupole moment and interaction in $\text{V}_x\text{Nb}_{1-x}\text{H}_y$, for example, is weaker than ^{181}Ta in Ta_2H and ^{175}Lu in $\text{LuH}_{0.20}$, for frequencies $f_{\max} < 24$ MHz, protons also cross relax to ^{93}Nb . When the proton resonance frequency matches one of the many spectral features of the metal NQR, spin polarization energy is transferred from the proton to the metal nucleus. The spin polarization energy is taken from the metal nucleus by the conduction electron interaction to the lattice because the contact hyperfine interaction is much stronger and thus faster (or higher rate) for the metal nucleus than for the proton. Figure 6 shows the proton cross relaxation to ^{181}Ta in $\text{TaH}_{0.32}$ as a function of proton resonance frequencies²⁴ (for a series of magnetic field values) while at $T = 130$ K. The calculation of the cross relaxation as a function of proton frequencies is described by Lichty et al.²⁴

Figure 5 Proton spin-lattice relaxation rates R_1 vs. $1000/T$ in LuH_x at 12, 40 and 65 MHz. Cross relaxation between the protons and the ^{175}Lu nuclear electric quadrupole broadened NMR lines can be seen at low temperatures in the loss of temperature dependence for $T \leq 400$ K. (Reproduced by permission of R. Oldenbourg Verlag from Torgeson et al.²³)

Figure 7 shows the total spin-lattice relaxation rate versus reciprocal temperature in schematic form, typical of many HMSs with the several component relaxation rates identified.

4 DEUTERON LINESHAPE FOR COMBINED ELECTRIC QUADRUPOLE AND KNIGHT SHIFTS

The Knight shift of hydrogen results from a small magnetic field at the hydrogen nucleus in an HMS from the conduction electron wave function $|\psi(0)|^2 \neq 0$ for the s electron character of the conduction electrons. This is often called the ‘contact hyperfine interaction’ or Fermi contact term. The application of the B_0 field causes a small paramagnetic polarization of the conduction electrons, called the Pauli paramagnetism, where $M_s = \chi_s B_0$ and χ_s is the Pauli spin susceptibility. χ_s can be related to the density $N(E_F)$ of unpaired conduction electron states at the top of the conduction electron distribution or at the Fermi energy via the Pauli susceptibility $\chi_s = \frac{1}{2}(\gamma_e h)^2 N(E_F)$. The Knight shift can be written simply as $K \approx \chi_s |\psi(0)|^2 / N$. The Knight shift causes a fractional change in the proton (deuteron) gyromagnetic ratio, that is, a small shift in position of the hydrogen resonance ΔH for fixed frequency or $\Delta \nu$ for

Figure 6 Proton cross-relaxation data (●) to ^{181}Ta nuclear electric quadrupole broadened NMR lines in $\text{TaH}_{0.32}$ as a function of a series of proton resonance frequencies at 130 K. See Lichty et al.²⁴ for details of the theoretical calculations and the three curves presented. The analysis yielded a ^{181}Ta nuclear electric quadrupole frequency $\nu_Q = 43$ MHz and electric field gradient asymmetry parameter $\eta = 0.35$. (Reproduced by permission of American Physical Society)

fixed field measurements

$$K = \frac{\Delta H}{H} = \frac{H_R - H_M}{H_R} = \frac{\Delta \nu}{\nu} = \frac{\nu_M - \nu_R}{\nu_R} \quad (9)$$

where subscript M refers to the metal field or frequency and R refers to the reference (solution or free ion) field or frequency. These fractional shifts are generally independent of the field or frequency.

Knight shifts of hydrogen in HMSs are generally quite small in magnitude compared with Knight shift values of metals, and often smaller in field shift magnitude ΔH than the dipolar broadened width or the B_L local magnetic field in the solid. However, the magnetic moment of the deuteron is smaller than the proton by a factor of 3.3, and effects of local magnetic fields are correspondingly smaller than for the proton. Figure 8 shows the combined effects of ^2D nuclear electric quadrupole interaction and Knight shifts²⁵ in a sample of $\text{NbD}_{0.76}$. The general subject of combined nuclear electric quadrupole interactions and Knight shift interactions in metals was first presented by Jones et al.²⁶ Since the ^2D spin $I = 1$, there are $2I + 1$ or 3 levels and two transitions and no ‘central line’. These two transitions for spin $I = 1$ are commonly referred to as the Pake doublet,²⁷ following the terminology established by George Pake in 1948 for the interaction of two coupled protons of combined spin $I = 1$ in the water of hydration in gypsum.

$\text{NbD}_{0.76}$ is orthorhombic in structure and thus the EFG and the Knight shifts must be described by tensors. The principal

Figure 7 Generalized proton spin–lattice relaxation rate R_1 contributions vs $1000/T$. These relaxation rates are: conduction electron, R_{1e} ; long range diffusion/dipole–dipole, R_{1d} ; paramagnetic impurity ion, R_{1p} ; and cross-relaxation to quadrupole (metal) nucleus, R_{1cr} . The relative weighting of these mechanisms depends on the purity and physical details of the HMS sample studied

axis system of the EFG has three separate components V_{xx} , V_{yy} , and V_{zz} , the second derivatives of the crystalline potential with respect to the coordinates x , y , and z . Note that $\nabla^2 V = V_{xx} + V_{yy} + V_{zz} = 0$ is Laplace's (electrical) equation. In the principal axis system, $|V_{xx}| < |V_{yy}| < |V_{zz}|$. The EFG asymmetry parameter for $\text{NbD}_{0.76}$ is $\eta = (V_{xx} - V_{yy})/V_{zz} = 0.11$. If η were equal to 0, then $V_{xx} = V_{yy}$ would require axial symmetry, i.e. at least three-fold rotational symmetry about the z axis. $\eta \neq 0$ implies the $\Delta m = \pm 1$ transitions $-1 \leftrightarrow 0$ and $0 \leftrightarrow +1$ in combination with the K_x , K_y , and K_z Knight shift components will produce different frequency dependences for the two transitions or ^2D 'powder' lineshapes.²⁵ The width of the pattern essentially measures the strength of the deuteron electric quadrupole interaction described by the lowest pure quadrupole frequency $\nu_Q = 3eQV_{zz}/2h = 49.3 \text{ kHz}$, where eQ is the deuteron quadrupole moment, V_{zz} is the principal component of the EFG tensor and h is Planck's constant. Incidentally, $\nu_Q = 3eQV_{zz}/[2I(2I-1)h]$ is the best measure of the strength of the quadrupole interaction relative to the strength of the NMR interaction characterized by ν_0 , the Larmor frequency.²⁸

For powdered metal hydrides with less than cubic crystal symmetry, the single grain particles' major symmetry axes will simply point in random directions in space. However, with an applied magnetic field switched on, the majority of particles' major symmetry axes will be nearly perpendicular to the field direction and a small minority of crystal symmetry directions will point along the field direction. This produces the well

Figure 8 (a) Deuteron absorption curve vs. frequency for $\text{NbD}_{0.56}$, (b) derivative of observed deuteron absorption curve, and (c) calculated deuteron absorption derivative curve lineshape. (Reproduced by permission of Academic Press from Torgeson et al.²⁵)

known $\sin \theta$ dependence of the distribution of powder particle orientations with respect to the magnetic field direction. As pointed out by Jones et al.²⁶ the major peaks of the absorption spectrum are due to 'singularities' at the perpendicular ($\theta = 90^\circ$) powder grains, and the smaller 'steps' at the extremes of the spectrum are due to those particle crystallites nearly parallel ($\theta = 0^\circ$) to the magnetic field.

The deuteron Knight shift, as for all hydrogen Knight shifts, originates from the contact hyperfine interaction of the conduction electrons at the deuteron (hydrogen) nucleus. In the HMS, the conduction electrons are attracted or 'cored' to the hydrogens in the same way conduction electrons are attracted to the metal nuclei. This, of course, makes the conduction electron wave functions more complex than in the pure metal, alloy, or intermetallic compound. The presence of

the hydrogen may actually change the electronic character of the HMS by changing the conduction electron wave functions and by the hydrogen donating an electron to the conduction band when hydrogen is absorbed, which may greatly modify the electronic band structure of the HMS.

The effect of the Knight shifts on the observed lineshape is simply a small displacement of the resonance position due to an additional magnetic field at the nucleus from the contact hyperfine interaction. For a non-cubic metal or HMS, the magnitude of the shift of the resonance is dependent upon orientation of the crystalline axes of the grain with respect to the field direction. Figure 8 (a) shows the observed absorption curve, (b) a derivative of the observed absorption and (c) a calculated absorption derivative with appropriate Knight shift and EFG components included. Absorption derivative lineshapes actually show more subtle lineshape features than do the absorption curves. Absorption derivatives lineshapes were commonly recorded in field or frequency scanned CW wideline studies in past years because of the use of lock-in amplifiers and small amplitude magnetic field or frequency modulation to record spectra.

5 LOW TEMPERATURE LOCAL HYDROGEN MOTION AND HYDROGEN TUNNELING IN HMSs

Scandium, yttrium, and lutetium plus other rare earth hcp metals provide a nearly unique opportunity to observe hydrogen dissolved in metals and measure hydrogen motions in metals at temperatures below 150 K. Unlike many transition metals, scandium, yttrium, and lutetium can maintain up to 30 at% hydrogen in solution without precipitating any of the hydride phase²⁹ down to 4 K or without transforming to another crystal structure.

Lichty et al.³⁰ measured proton R_1 s in $\text{ScH}_{0.27}$ ($\text{H}_{0.18}$) and found both an electronic relaxation R_{1e} and a weak low temperature motional relaxation peak R_{1L} near 60 K (105 K). That peak moved with the proton resonance frequency in a manner similar to the movement of R_{1d} , the over the barrier hopping, long range diffusion relaxation rate peak at much higher temperatures. In Figure 9 we see these low temperature data for two proton frequencies. The R_{1L} motional relaxation peak is superimposed on the R_{1e} electronic relaxation, which is linear in temperature T ($R_{1L} = R_1 - R_{1e}$; R_{1L} will be discussed below).

The location of hydrogen (deuterons) in the scandium hcp lattice was studied by neutron scattering.²⁹ Deuterons were found to prefer to form pairs with a scandium atom between. From these neutron scattering studies, models of hydrogen ordering in chains of paired hydrogens in scandium were proposed.

The pairing of hydrogen with a scandium metal between is an interesting and unusual ordering. However, not all hydrogens are paired with a metal between. Some of the hydrogens are unpaired and thus occupy vacant tetrahedral (T) sites in a random or inhomogeneous manner. The random occupation of hydrogen in metal–solid solutions has been referred to by Barnes¹⁴ as a proton glass. The result of an inhomogeneous hydrogen occupation can be seen in the proton spin–lattice relaxation rate data and will be explained below.

The scandium hcp lattice has two adjacent, closely spaced interstitial T sites along the c axis where hydrogen is known²⁹

Figure 9 Proton spin–lattice relaxation rate (R_1) in $\text{ScH}_{0.27}$ as a function of temperature at 24 and 62 MHz. Proton R_1 in $\text{YH}_{0.18}$ at 24 MHz ($\bullet$) shows a weak peak at ~ 105 K. The peak heights are due to the relaxation of the proton's tunneling motion and proton dipole 'collisions' with fixed (^{45}Sc or ^{89}Y) metal nuclear magnetic moments. Note the ^{89}Y moment is $<1/20$ of the ^{45}Sc moment. (Reproduced by permission of the American Physical Society from Lichty et al.³⁰)

to sit in one of the sites. These two sites are too closely spaced to permit two hydrogens to occupy both sites simultaneously.³¹ The local motion is understood to be one hydrogen moving between these two closely spaced T sites. Activation energies derived from a 'local over a small barrier' hopping model were found to be $E_a \approx 50$ meV, much smaller than the nominal 500 meV activation energies typical of long-range hopping over a barrier found for activation energies in higher temperature hydrogen diffusion. Lichty et al.³⁰ were able to fit the proton spin–lattice relaxation rates versus $1000/T$ with two separate and quite different models for hydrogen hopping over an energy barrier. As can be seen from Figure 10, the data are not symmetrical about the peaks of the three relaxation curves. The slope of the three curves on the high temperature (low $1/T$ values) side of the peak is much greater than the low temperature (higher $1/T$ values) slopes. Symmetrical $\log R_1$ versus $1/T$ curves in HMSs is a signature of hydrogen hopping where there is one unique activation energy typifying a simple hopping process and/or a simple and often cubic solid. Symmetrical $\log R_1$ or $\log T_1$ vs $1/T$ curves are often referred to as BPP type behavior. The relaxation rate curves in Figure 10 show the signature of hydrogen motion in a disordered solid with a distribution of activation energies. This subject will be discussed at length below. Lichty et al.³⁰ were able to fit the data with two hopping models, one assuming a distribution of activation energies and a second model with a correlation

Figure 10 Proton spin–lattice relaxation rate in $\text{ScH}_{0.27}$ vs. $1000/T$ for proton resonance frequencies 12, 40, and 90 MHz fitted with a thermally activated over the barrier hopping model and a distribution of activation energies. (Reproduced by permission of the American Physical Society from Lichty et al.³⁰)

function having a stretched exponential character. Localized hydrogen motion has also been found by Skripov et al.³² in TaV_2H_x in the temperature range 10–100 K.

Tunneling of hydrogen from one tetrahedral interstitial site to an adjacent empty T site at low temperature is an alternate mechanism rather than hydrogen thermally activated hopping over a low energy barrier. Svare et al.³³ suggested that the same proton spin–lattice relaxation data of Lichty et al.³⁰ in $\text{ScH}_{0.27}$ could also be described by hydrogen tunneling between adjacent T sites in the Sc hexagonal close packed lattice. The potential wells for the two sites were thought to have sinusoidal curvature near the bottoms. The two wells of the adjacent T sites were also thought to have different minimum energies, that is, the wells were asymmetric. In fact, Svare et al.³³ suggested the asymmetry, A , for the hydrogen–scandium metal solid solution would have a distribution of minimum energy difference values typical of an inhomogeneous hydrogen solid solution or proton glass. With increasing temperature, the tunneling model must include a tunneling mechanism not appropriate (or yet thermally switched on) at lower temperature. Figure 11 shows the proton spin–lattice relaxation data of Lichty et al.³⁰ fit with this tunneling model. The data fit adequately this tunneling theory and support the proposition that hydrogen tunneling exists in scandium at low temperatures. Hydrogen tunneling in scandium was also found by Leisire et al.³⁴ in a resonant ultrasound spectroscopy (not an NMR technique) study of $\text{ScH}_{0.25}$ and $\text{ScD}_{0.18}$ employing small scandium single crystals.

6 SPIN–LATTICE RELAXATION IN AMORPHOUS HYDROGEN–METAL SYSTEMS

An amorphous metal alloy may be formed by extremely rapid cooling of the molten metal alloy. Such materials are often referred to as metallic glasses. An amorphous alloy is a

Figure 11 Low temperature proton spin-lattice relaxation rates $R_{\text{IL}} \equiv T_{\text{IL}}^{-1}$ versus reciprocal temperature in two hcp scandium–hydrogen solid solution compositions. (a) $\text{ScH}_{0.27}$ and (b) $\text{ScH}_{0.11}$ at 24 MHz (+), 40 MHz (x), and 90 MHz (•), respectively. The curves represent the fits of the tunneling model with a distribution of asymmetric energy well minima for hydrogen tunneling between adjacent tetrahedrally coordinated interstitial (T) sites. Data are from Lichty et al.³⁰ and tunneling model can be found in Svare et al.³³

disordered metal and is without long range topological order. There may be short range or compositional order in amorphous alloys. These amorphous materials are then hydrided by more or less conventional means, but care must be taken not to heat the material high enough to ‘recrystallize’ the amorphous sample. This may be somewhat difficult as the absorption of hydrogen by metals is generally an exothermic reaction.

Bowman³⁵ points out that metallic alloy glasses must contain one of certain metals, i.e. titanium, zirconium, hafnium, palladium, or a rare earth metal, for the glass to be able to hold hydrogen, $\text{H}/\text{M} > 0.1$, where M is the total metal content. Even with one of these metals in the alloy, an alloy glass may not be formed upon quenching.

Hydrides of metallic glasses generally have quite different hydrogen motions, with lower hydrogen diffusion activation energies and spin–lattice relaxation rates than do hydrides of the crystalline HMSs of similar composition as we shall see below. In the case of crystalline and amorphous Zr_2PdH_x , Bowman et al.³⁶ point out the $\log T_1$ versus $1000/T$ plots for $\text{Zr}_2\text{PdH}_{2.90}$ and amorphous $\text{a-Zr}_2\text{PdH}_{2.90}$ are noticeably

Figure 12 Proton spin-lattice relaxation times vs. $1000/T$ for crystalline $\text{Zr}_2\text{PdH}_{1.84}$ and $\text{Zr}_2\text{PdH}_{2.90}$ at 40 MHz and amorphous $\text{Zr}_2\text{PdH}_{2.90}$ at 34.5 MHz, and proton relaxation times for crystalline and amorphous $\text{Zr}_2\text{PdH}_{2.90}$ vs. $1000/T$. The latter curve shows hydrogen diffusion at lower temperatures and with lower activation energy (slope of T_1 vs. $1000/T$ curve) than the crystalline $\text{Zr}_2\text{PdH}_{2.90}$. (Reproduced by permission of R. Oldenbourg Verlag from Bowman et al.³⁶)

different. The crystalline and amorphous curves have minima at different temperatures and have different slopes or diffusion activation energies. Generally, the amorphous samples display more rapid hydrogen diffusion at lower temperatures and have lower activation energies for diffusion than do the crystalline equivalents. This can be seen in Figure 12. A simplistic explanation of this effect may relate in part to the fact that the glassy HMSs have a somewhat lower density and have more 'open' paths for hydrogen to hop through than the crystalline equivalents. A more complete description of hydrogen motion must also include the differences in electronic character known to exist between the glassy and crystalline HMSs.

1 INTRODUCTION

Inorganic chemistry is a vast discipline dealing with more than 100 elements, many of which have at least one magnetically active isotope that is suitable for recording its high-resolution NMR spectra in solution and in the solid state. Therefore, application of NMR (today one strives for an approach using multinuclear magnetic resonance)^{1,2} has contributed considerably to the development of inorganic chemistry and also to the present vigorous research activity. This article cannot cover all aspects involved. Therefore examples of important applications in various fields of inorganic chemistry will be given. These examples are confined to diamagnetic samples such as liquids or solids, although there are numerous inorganic chemistry applications of NMR to paramagnetic samples. The NMR techniques employed and the physical background of the NMR parameters are dealt with elsewhere in the Encyclopedia as indicated by the cross references at the end of the article.

The nuclides of particular interest for inorganic chemistry applications range from ${}^1\text{H}$, with the greatest magnetic moment of all naturally occurring nuclides, to heavy metal nuclides like ${}^{207}\text{Pb}$, including those with both a small magnetic moment and low natural abundance (e.g. ${}^{57}\text{Fe}$ or ${}^{187}\text{Os}$). For many applications the different relaxation behavior of spin- $\frac{1}{2}$ and quadrupolar nuclides (spin $I \geq 1$) must be considered.

Chemical shifts (δX), indirect nuclear spin–spin coupling or scalar coupling [${}^nJ(A,X)$], and the nuclear relaxation properties (represented by the relaxation rate constants T_1^X , T_2^X) are the prominent NMR parameters. For both liquid and solid samples these data can be related to the structure and to various types of dynamic processes such as motion in solids, inter- or intramolecular exchange and molecular dynamics in solution. Structural changes and in general all types of chemical processes are reflected by characteristic changes in the NMR parameters.

The δX value (Section 2) as a measure of nuclear magnetic shielding characterizes the chemical neighborhood of the nucleus X if a sufficiently large δX data set is available for comparison. Thus, for a new compound with unknown structure the parameter δX indicates the nature of groups linked to X and, frequently, it is possible to evaluate the

coordination number of X (CN_X). This means of course that important structural information can be gained by comparing solid- and liquid-state δX values. The dependence of δX values on particular properties of the electronic structure implies that changes in δX are related to changes in other spectroscopic properties, e.g. to the λ values for magnetic-dipole-allowed electronic transitions in UV spectra. From solid state NMR spectra one can obtain more detailed information on nuclear magnetic shielding by analysis of the anisotropic contributions.

The magnitude and sign of coupling constants measured for NMR-active nuclides, ${}^nJ(A,X)$ (Section 3; heteronuclear or homonuclear spin–spin coupling), depend on the structural relationship between the nuclides since this interaction is electron mediated. In order to compare J values for various nuclides A and X it is advisable to use the reduced coupling constants K instead. These K values are independent of the individual nuclear magnetic properties of the respective nuclides: $K(A,X) = 4\pi^2 \cdot J(A,X) \cdot (h \cdot \gamma_A \cdot \gamma_X)^{-1}$. The splitting pattern in the A or the X NMR spectrum indicates the number of X or A, respectively, and can be analyzed as a first or higher order spectrum according to the spin system. Furthermore, in solution, the parameters ${}^nJ(A,X)$ enable us to carry out a great variety of NMR experiments (e.g. based on spin polarization transfer) for tracing the connectivity of NMR-active nuclides within the same molecule.

Relaxation rate constants T_1^X (longitudinal or spin–lattice relaxation time), T_2^X (transverse or spin–spin relaxation time), and $T_{1\rho}^X$ (spin–lattice relaxation time in the frame of reference rotating with $\mathbf{B}_1$) reveal a wealth of information on solution- and solid state properties (Section 4) if the contributions according to the respective relaxation mechanism can be determined. Thus, NOE measurements or dipolar spin–spin coupling constants enable us to assess internuclear distances, e.g. $d_{X-1\text{H}}$ or d_{X-X} . Other important information concerns the thermodynamic parameters and the mechanism of exchange processes, quadrupolar interactions in solution and in solids, anisotropic motion in solution, and all types of motion in solids.

2 APPLICATION OF CHEMICAL SHIFTS δX

2.1 Chemical Shifts $\delta^1\text{H}$ and $\delta^{13}\text{C}$

Although less dominant compared with organic chemistry applications, ${}^1\text{H}$ NMR studies play a major role in inorganic chemistry. Looking at inorganic compounds, we find that the range of $\delta^1\text{H}$ values [internal reference $(\text{CH}_3)_4\text{Si}$] known for most organic compounds ($\delta^1\text{H}$ 0 to +10) is increased at both ends. Important examples are the ${}^1\text{H}$ resonance signals shifted toward high frequency ($\delta^1\text{H}$ +10 to +20) if hydrogen atoms are involved in so-called strong hydrogen bonding³ (e.g. $[\text{FHF}]^-$ or $[\text{H}(\text{NO}_3)_2]^-$) and the ${}^1\text{H}$ NMR signals of transition metal hydrides which can be found at rather low frequency⁴, e.g. in the range of $\delta^1\text{H}$ 0 to –50. This range is not fixed since there are also some examples of ${}^1\text{H}$ NMR signals of transition metal hydrides at higher frequencies, e.g. in the case of some clusters containing interstitially bonded hydrogen atoms. The pH dependence of $\delta^1\text{H}$ values as the result of hydrogen bridging enables us to determine pK_a values if other methods are not straightforward.

Thus the pK_a values of cis -[PtCl(H₂O)(NH₃)₂]⁺ (5.37) and cis -[Pt(H₂O)₂(NH₃)₂]²⁺ (7.21), the hydrolysis products of 'cisplatin', cis -[PtCl₂(NH₃)₂], have been determined by using ¹⁵N-edited ¹H NMR.⁵

Most ¹H NMR applications deal with liquids. Of course, solid state ¹H NMR studies are also very attractive, but strong dipolar interactions between protons cannot be removed solely by MAS. Even by using advanced techniques like CRAMPS, the necessary resolution of separate ¹H NMR signals is difficult to achieve because of broadened signals and the rather small range of ¹H chemical shifts. If the hydrogen content of solids is low, e.g. in zeolites, narrow ¹H NMR signals can be expected.⁶ A value of $\delta^1H \approx 7$ has been assigned to catalytically active acidic hydroxyl groups.

Application of δ^2H (²H: $I = 1$) plays a minor role in inorganic chemistry. The δ^1H and δ^2H values can be regarded as identical.

Values of $\delta^{13}C$ [reference Si(CH₃)₄] of the carbonyl ligand in metal–carbonyl complexes⁷ are characteristic of the respective metal and of the nature of metal–carbon bonding, e.g. for a terminal or a bridging carbonyl group (μ -CO), the ¹³C nuclide of the latter being significantly deshielded, as shown for $\delta^{13}C$ ranges of Fe-, Ru-, Co-, and Rh-carbonyl compounds (Figure 1). In particular for transition metal carbonyl clusters, ¹³C-enriched material (≈ 10 –20%) is commonly used. The high-frequency ¹³C NMR signals typical of carbene and carbyne–metal complexes ($\delta^{13}C$ 200–400) are noteworthy since they are mostly far outside the $\delta^{13}C$ range for organic compounds (0–220). Similar to organic chemistry applications, there is a wealth of $\delta^{13}C$ data for all types of organic ligands attached to metals.⁷

Carbon-13 nuclear shielding in solids is increasingly used in inorganic chemistry. Examples of applications are carbonates which have only a small range (3.6 ppm) of $\delta^{13}C$ values⁸ and carbides with a large range (>100 ppm) of $\delta^{13}C$ values.⁹

2.2 Chemical Shifts of Some Other Spin- $\frac{1}{2}$ Nuclides

2.2.1 ²⁹Si

Chemical shifts $\delta^{29}Si$ [external reference Si(CH₃)₄] cover a range of ≈ 600 ppm.^{1,2,10} These data are extremely useful for determining structural principles of silicates in solution¹¹ and in the solid state.¹² Major applications concern zeolites where the different sites of silicon atoms according to the structure of the zeolite can be determined and also the number of Si–O–Al bridges for a particular silicon atom. The latter is evident from ²⁹Si nuclear deshielding with an increasing number of Si–O–Al bridges (Figure 2). In silicone polymers, separate

Figure 1 Carbon-13 chemical shift ranges of Fe-, Ru-, Co-, and Rh-carbonyl compounds

Figure 2 Silicon-29 chemical shift ranges of zeolites with different surroundings of the silicon in tetrahedral SiO₄ moieties

Figure 3 Silicon-29 chemical shift ranges in silanes with Si–O and Si–C bonds

²⁹Si NMR signals are found for the basic structural units, such as Me₃Si–O–, Me₂Si(O–)₂, MeSi(O–)₃ and Si(O–)₄ (Figure 3).

In the case of three-coordinate silicon atoms, e.g. in Si–element double bonds, ²⁹Si NMR signals are shifted to higher frequencies, similar to the situation for $\delta^{13}C$ in alkenes or ketones. If $CN_{Si} > 4$, the ²⁹Si nuclear shielding increases significantly. For solutions of decamethylsilicocene [(η^5 -C₅Me₅)₂Si], a single ²⁹Si NMR signal is found at very low frequency ($\delta^{29}Si = -398.0$). In the solid state, there are two ²⁹Si NMR signals,¹³ one for the bent structure ($\delta^{29}Si = -403.2$) and the other one ($\delta^{29}Si = -423.4$) for the silicon atom with a parallel arrangement of the C₅Me₅ rings in a ratio of 2:1, in agreement with the results of X-ray analysis.

2.2.2 ¹¹⁹Sn, ²⁰⁷Pb

Values of $\delta^{119}Sn$ [external reference Sn(CH₃)₄] cover a range of ≈ 5000 ppm,^{1,2,14} compared with a range of ≈ 17 000 ppm for $\delta^{207}Pb$,^{1,2,15} with tin(II) or lead(II) compounds at both ends (Table 1): The lowest ¹¹⁹Sn, ²⁰⁷Pb nuclear shielding is observed for monomeric stannylenes or plumbylenes, SnR₂, PbR₂ [R = bulky organyl group, e.g. (Me₃Si)₂CH], whereas high ¹¹⁹Sn, ²⁰⁷Pb nuclear shielding is typical of stannocenes and plumbocenes.¹³

As for other heavy nuclides, both ¹¹⁹Sn and ²⁰⁷Pb nuclear shieldings are very sensitive toward small structural changes and, therefore, readily reflect strong or weak coordination in Lewis acid/Lewis base interactions. Thus, the temperature-, solvent-, and concentration-dependence of $\delta^{119}Sn$ and $\delta^{207}Pb$

Table 1 Extreme Values for ¹¹⁹Sn and ²⁰⁷Pb Chemical Shifts

	[(Me ₃ Si) ₂ CH] ₂ M	[(Me ₃ Si) ₂ N] ₂ M	(η^5 -C ₅ Me ₅) ₂ M
$\delta^{119}Sn$	+2320	+776	–2129
$\delta^{207}Pb$	+9110	+4916	–4390

data is of interest, and the comparison of $\delta^{119}\text{Sn}$ and $\delta^{207}\text{Pb}$ data in the solid and liquid state is particularly attractive.

2.2.3 ^{15}N

In spite of its low natural abundance (0.37%) and its unfavorable nuclear magnetic properties (low and negative $\gamma^{15}\text{N}$), ^{15}N NMR measurements of both nonlabeled and ^{15}N -labeled (bioinorganic applications) nitrogen compounds are becoming increasingly attractive.¹⁶ The application of $\delta^{15}\text{N}$ values has a potential similar to that of $\delta^{13}\text{C}$. Values of $\delta^{15}\text{N}$ (identical with $\delta^{14}\text{N}$; external reference neat CH_3NO_2) cover a range of ≈ 1300 ppm, and the trends in changes of N atom nuclear shielding are similar to those of ^{13}C in corresponding carbon compounds (e.g. the linear relationship of $\delta^{15}\text{N}/\delta^{13}\text{C}$ data of linear compounds such as $\text{N}\equiv\text{N}/[\text{C}\equiv\text{N}]^-$, $\text{C}_4\text{H}_9-\text{C}\equiv\text{N}/[\text{C}_4\text{H}_9-\text{C}\equiv\text{C}]^-$, $[\text{H}-\text{C}\equiv\text{N}-\text{H}]^+/\text{H}-\text{C}\equiv\text{C}-\text{H}$, $[\text{NO}]^+/\text{CO}$, $\text{NO}_2^+/\text{CO}_2$, $\text{N}=\text{N}=\text{O}/[\text{N}=\text{C}=\text{O}]^-$, $[\text{C}_6\text{H}_5-\text{N}\equiv\text{N}]^+/\text{C}_6\text{H}_5-\text{N}\equiv\text{C}$, $[\text{C}_6\text{H}_5-\text{N}\equiv\text{N}]/\text{C}_6\text{H}_5-\text{C}\equiv\text{N}$: $\delta^{13}\text{C} = 0.536$, $\delta^{15}\text{N} = +196.5$). Extreme shielding [e.g. in $\text{N}(\text{SiH}_3)_3$: $\delta^{15}\text{N} -417.7$] and deshielding [e.g. in $(\text{CH}_3)_3\text{Si}-\text{N}=\text{N}-\text{Si}(\text{CH}_3)_3$: $\delta^{15}\text{N} +618$] of nitrogen nuclides is observed for inorganic nitrogen compounds. An example for the high sensitivity of N atom nuclear shielding to changes in the electronic structure is given by comparing $\delta^{15}\text{N}$ values of bent and linear $\text{M}-\text{NO}$ arrangements [the NO group functions as one-electron (bent) or three-electron donor (linear)]. In all cases studied, confirmed by the results of X-ray analyses and solid state ^{15}N NMR measurements, the bent structure causes considerable deshielding of the ^{15}N nucleus. The same is true for the azenido ligand in complexes with a linear or a bent MNR arrangement.¹⁷

2.2.4 ^{31}P

The ^{31}P nucleus is one of the 'traditional' nuclides since it was relatively easy to measure ^{31}P NMR spectra, even in the early days of NMR. Today, ^{31}P NMR is of prime importance in phosphorus chemistry,^{18,19} and chemical shifts $\delta^{31}\text{P}$ serve as convenient parameters for identifying reaction products or monitoring the progress of reactions. In this context the huge range of $\delta^{31}\text{P}$ values (external reference H_3PO_4 , 85% aq) of almost 2000 ppm is very helpful, although there is no decided dependence on CNP or on the formal oxidation state of phosphorus (see, e.g., Tables 2 and 3). The extreme bonding situation in inorganic phosphorus compounds is reflected by examples with very high ^{31}P nuclear shielding (e.g. P_4 : $\delta^{31}\text{P} -488$) or deshielding [e.g. $(\text{CH}_3)_3\text{C}-\text{P}[\text{Cr}(\text{CO})_5]_2$ $\delta^{31}\text{P} +1362$].²⁰ Major applications of $\delta^{31}\text{P}$ values can be found in the chemistry of polyphosphanes,²¹ in the investigation of low-coordinated phosphorus compounds, with or without phosphorus–element multiple bonds (e.g. element = C, Si, Ge, Sn, N, P), and in the transition metal chemistry involving the countless number of metal–phosphane complexes.

Like solid state ^{29}Si NMR in silicates, solid state ^{31}P NMR of all kinds of phosphates²² is extensively studied. Even very small changes in the crystal structure of phosphates are reflected by changes in the isotropic chemical shifts $\delta^{31}\text{P}$.

2.2.5 ^{77}Se , ^{125}Te

Chemical shifts $\delta^{77}\text{Se}$ [external reference $(\text{CH}_3)_2\text{Se}$; range $\approx +2000$ to -800] and $\delta^{125}\text{Te}$ [external reference $(\text{CH}_3)_2\text{Te}$;

range $\approx +3300$ to -1200] are related by a factor of ≈ 1.6 – 1.8 for analogous compounds.²³ Important inorganic chemistry applications deal with the studies of cluster cations, e.g. $[\text{Se}_n\text{Te}_m]^{2+}$ (Table 4) for which the $\delta^{77}\text{Se}$ and $\delta^{125}\text{Te}$ values cover ranges of ≈ 1400 and ≈ 3000 ppm, respectively.²⁴

2.2.6 ^{19}F

The high NMR sensitivity of ^{19}F (second to ^1H), the considerable range (≈ 1300 ppm) of the $\delta^{19}\text{F}$ values (external reference neat CFCl_3) and the frequently extreme character of many fluorine–element bonds (as a result of the high electronegativity of fluorine) has led to many applications

+584	+1613	355 Hz	31 Hz	120 Hz

of ^{19}F nuclear shielding.²⁵ Like ^1H NMR of organic or organometallic compounds, ^{19}F NMR is extremely useful in the analysis of mixtures of fluorine compounds, e.g. equilibrium mixtures of element-halides such as WF_6 and WCl_6 , BF_3 , BCl_3 and BBr_3 (Figure 4), or anionic species such as $[\text{BF}_4]^-$ and $[\text{BCl}_4]^-$.

Many inorganic fluorides are insoluble solids, some of which have been studied by various solid state NMR techniques.²⁶ Thus, changes in $\delta^{19}\text{F}$ values of solid alkali-metal fluorides appear to be a function of the cation electronegativity. In principle, high-resolution solid state ^{19}F NMR spectra would be of great interest. However, this field is not very well developed so far, since it suffers to some extent from similar physical and instrumental problems as high-resolution solid state ^1H NMR spectra.

2.2.7 ^{129}Xe

Chemical shifts $\delta^{129}\text{Xe}$ (external reference XeOF_4) cover a range of ≈ 7000 ppm,²⁷ including gaseous xenon ($\delta^{129}\text{Xe} \approx -5300$, depending on solvent, temperature, or if xenon is a guest atom, e.g. in clathrates or zeolites). With few exceptions, the ^{129}Xe nuclides become more deshielded with the higher the oxidation state of Xe. The most deshielded example is found in an aqueous solution of Na_2XeO_6 ($\delta^{129}\text{Xe} = +2077$). Clearly, ^{129}Xe NMR is a major tool in xenon chemistry in the well-established field of xenon-fluorine and xenon-oxygen compounds as well as in the new and exciting field of xenon-carbon compounds.

2.2.8 Some Transition Metal Spin- $\frac{1}{2}$ Nuclides (^{57}Fe , ^{103}Rh , ^{109}Ag , ^{113}Cd , ^{199}Hg , ^{183}W , ^{195}Pt)^{1,2,28}

Although iron chemistry is a very important field, $\delta^{57}\text{Fe}$ values have found only limited applications. This is mainly due

Figure 4 Fluorine-19 NMR spectrum at 75.3 MHz of an equilibrated mixture of BF_3 , BCl_3 and BBr_3 : the boron halides BFBr_2 , BFCIBr , BF_2Br and BF_2Cl cannot be isolated in the pure state. Note the splitting of the ^{19}F NMR signals due to $^1J(^{19}\text{F}, ^{11}\text{B})$

to the low NMR sensitivity of ^{57}Fe . In principle, $\delta^{57}\text{Fe}$ values [external reference $\text{Fe}(\text{CO})_5$] are sensitive to small changes in the iron-ligand sphere and cover a large range, considering, e.g., diene $\text{Fe}^{(0)}$ complexes ($\delta^{57}\text{Fe} \approx -600$ to $\approx +1700$) or ferrocene (Cp_2Fe) derivatives and other cyclopentadienyl iron compounds ($\delta^{57}\text{Fe} \approx +1000$ to $\approx +5100$). An increase in ^{57}Fe nuclear shielding in α -ferrocenyl carbocations indicates the fulvenoid character and the presence of an $\text{Fe}-\text{C}-\alpha$ bond, whereas ^{57}Fe deshielding points toward a nonfulvenoid structure together with the influence of an electron deficient substituent (Table 5). Extreme deshielding of ^{57}Fe is observed in myoglobin derivatives with $\delta^{57}\text{Fe} \approx +7200$ to $+8200$.

With modern NMR instruments ^{103}Rh NMR spectra can easily be measured and many $\delta^{103}\text{Rh}$ data {the absolute frequency $\Xi^{103}\text{Rh} = 3.16$ MHz [$\Xi^1\text{H}(\text{Me}_4\text{Si}) = 100.00$ MHz] serves as reference} are known, covering a large range ($\delta^{103}\text{Rh} \approx +10\,000$ to -2000). The extreme examples are the cation $[\text{Rh}(\text{H}_2\text{O})_6]^{3+}$ ($\delta^{103}\text{Rh} = +9992$), $[\text{Rh}(\text{acac})_3]$ ($\delta^{103}\text{Rh} = +8358$) and the rhodium(I) sandwich complex $[(\eta^5\text{-C}_5\text{H}_5)\text{Rh}(\eta^4\text{-C}_4\text{H}_4)]$ ($\delta^{103}\text{Rh} = -2057$). There is no correlation between $\delta^{103}\text{Rh}$ and the formal oxidation state of rhodium. The cluster chemistry of rhodium is well developed, also with respect to the structure and dynamic properties in solution. This has been achieved by measurement of $\delta^{103}\text{Rh}$ values either directly by using ^{103}Rh NMR or indirectly via heteronuclear double resonance experiments, e.g. $^{13}\text{C}\{^{103}\text{Rh}\}$ in rhodium clusters bearing ^{13}C -labeled carbonyl ligands (Figure 5).²⁹

The major applications of $\delta^{109}\text{Ag}$ values (identical with $\delta^{107}\text{Ag}$; external reference Ag^+ at infinite dilution in H_2O or the absolute frequency $\Xi^{109}\text{Ag} = 4.653\,623$ MHz) concern the complexation behavior of Ag^+ cations in various solvents and in the presence of various ligands. The $\delta^{109}\text{Ag}$ values thus obtained cover a range of ≈ 1500 ppm to high frequency of the reference.

Chemical shifts $\delta^{113}\text{Cd}$ [identical with $\delta^{111}\text{Cd}$; external reference $\text{Cd}(\text{ClO}_4)_2(\text{aq})$ 0.1 M; or neat $(\text{CH}_3)_2\text{Cd}$ ($\Xi^{113}\text{Cd} = 22.193\,173$ MHz) with $\delta^{113}\text{Cd} = +641.0$] cover a range of ≈ 1000 ppm to high frequency of the reference. The $\delta^{113}\text{Cd}$ values have been used to establish the equilibria involved between halide anions and Cd^{2+} ions in various solvents or of species such as $[\text{CdX}_4]^{2-}$ with $\text{X} = \text{Cl}, \text{Br}, \text{I}$ or SCN . Numerous chemical shifts $\delta^{113}\text{Cd}$ have been measured for solid cadmium compounds. In some of these the ^{113}Cd nuclear shielding is

	+2867	+4489	+6760

increased with respect to the reference owing to the nature of the ligand and $\text{CN}_{\text{Cd}} = 6$ (e.g. in solid CdI_2 : $\delta^{113}\text{Cd} = -677$) or $\text{CN}_{\text{Cd}} = 8$ (e.g. in solid $\text{Cd}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$: $\delta^{113}\text{Cd} = -100$ or in solid CdF_2 : $\delta^{113}\text{Cd} = -288$).

Chemical shifts $\delta^{199}\text{Hg}$ [external reference $\text{Hg}(\text{ClO}_4)_2$ (0.1 M in 0.1 M HClO_4), corresponding to $\Xi^{199}\text{Hg} = 17.870$ 535 MHz or neat $(\text{CH}_3)_2\text{Hg}$ ($\delta^{199}\text{Hg} = +2255$) with $\Xi^{199}\text{Hg} = 19.910$ 841 MHz] have been reported for all types of mercury compounds with a range from ≈ -1200 (HgI_2 in tetrahydrofuran) to $\approx +3070$ {neat $[(\text{C}_2\text{H}_5)_3\text{Si}]_2\text{Hg}$ }.³⁰ Attempts have been made to characterize the poorly defined nature of mercury salts in aqueous and other solutions by the change in ^{199}Hg nuclear shielding. Similarly, $\delta^{199}\text{Hg}$ values can be used to determine the binding site (e.g. to O, N or S) of $[\text{MeHg}]^+$ cations. In the case of organomercury compounds, it is possible to measure $\delta^{199}\text{Hg}$ values even from very dilute solutions (e.g. aqueous solutions of ethylmercury phosphates and their interaction with amino acids) by taking advantage of indirect (^1H -detected) methods, based on scalar ^{199}Hg – ^1H spin–spin coupling. High-resolution solid state ^{199}Hg NMR measurements are feasible in the case of tetrahedral mercury complexes, e.g. $[\text{Hg}(\text{SR})_4]^{2-}$, otherwise the huge anisotropy of ^{199}Hg nuclear shielding causes problems.

Major applications of $\delta^{183}\text{W}$ values (referred to a ≈ 1 M solution of Na_2WO_4 in D_2O with $\text{pD} = 9$; or WF_6 : $\delta^{183}\text{W} = -1121$ with $\Xi^{183}\text{W} = 4.161$ 733 MHz) concern the structural characterization of polytungstates and heteropolytungstates in solution.³¹ Other tungsten compounds studied are mostly those with a W–F, W–P, or W–H bond, using indirect detection of the ^{183}W resonances or polarization transfer, taking advantage of scalar ^{183}W – ^{19}F , ^{183}W – ^{31}P or ^{183}W – ^1H spin–spin coupling. Further examples of the application of $\delta^{183}\text{W}$ comprise carbyne complexes and dinuclear complexes with WW double and quadruple bonds (Table 6).

The favorable nuclear magnetic properties of ^{195}Pt and the well-developed platinum chemistry guarantee numerous applications of $\delta^{195}\text{Pt}$ values {external reference is the absolute frequency $\Xi^{195}\text{Pt} = 21.4$ MHz [$\Xi^1\text{H}$ (Me_4Si) = 100.00 MHz] or the $\text{Na}_2[\text{PtCl}_6]$ in D_2O with $\Xi^{195}\text{Pt} = 21.496$ 770 MHz corresponding to $\delta^{195}\text{Pt} = +4522$ }. The range of $\delta^{195}\text{Pt}$ values covers ≈ 15 000 ppm {[PtF_6] $^{2-}$: $\delta^{195}\text{Pt} \approx +11$ 840; many $\text{Pt}(0)$ and $\text{Pt}(\text{II})$ complexes have $\delta^{195}\text{Pt}$ values up to -3000 }. There is no clear dependence of $\delta^{195}\text{Pt}$ values on the formal oxidation state of the metal. The analysis of mixtures of platinum compounds is readily achieved since the dispersion of $\delta^{195}\text{Pt}$ values is much larger than that of $\delta^{13}\text{C}$ or $\delta^1\text{H}$ for the respective ligands. This is helpful for monitoring reactions and for assigning the structures of the final products, e.g. to distinguish between diastereomers. High-resolution solid state ^{195}Pt NMR spectra are relatively simple for octahedrally surrounded platinum and become complex and much more

difficult to measure in the case of square-planar platinum complexes because of the large anisotropy of ^{195}Pt nuclear shielding.

2.3 Chemical Shifts of Some Quadrupolar Nuclides

2.3.1 ^6Li , ^7Li , ^{23}Na , ^{39}K , ^{87}Rb , ^{133}Cs ^{1,2}

The range of chemical shifts δLi [external reference $\text{Li}^+(\text{aq})$] is small (≈ 15 ppm). However, in accord with the usual trend, the range of δ values for the heavier nuclides [external references: $\text{M}^+(\text{aq})$] of this group increases with the mass of the nuclides and, therefore, it is possible to study the influence of the counterion, and of solvent effects, including the function of cryptands and concentration effects on the nuclear shielding of the cations, in great detail. Furthermore, the formation of the metal anions $[\text{Na}]^-$, $[\text{K}]^-$, $[\text{Rb}]^-$, and $[\text{Cs}]^-$ (alkalides) is readily proved (Table 7) by the extreme shifts of the NMR signals to low frequency³² as a consequence of the ns^2 electron configuration.

2.3.2 ^9Be ,^{1,2} ^{25}Mg ³³

Limited applications have been found for $\delta^9\text{Be}$ and $\delta^{25}\text{Mg}$ [external references: $\text{Be}^{2+}(\text{aq})$ and $\text{Mg}^{2+}(\text{aq})$], with respect to both changes in coordination number and in CpBe and CpMg derivatives.

2.3.3 ^{11}B

The nuclear shielding of ^{11}B has received considerable attention. A large data set of chemical shifts $\delta^{11}\text{B}$ (external reference $\text{Et}_2\text{O}-\text{BF}_3$) is available for all types of boron compounds in solution.^{34,35} Low nuclear shielding of boron ($\delta^{11}\text{B} \approx +10$ to $+130$) is observed for three-coordinate boron (Table 8), depending on the electronic structure of the boranes. An interstitial boron atom in the anion $[\text{Ru}_6(\text{H})_2(\text{CO})_{18}\text{B}]^-$ represents the most deshielded ^{11}B nucleus ($\delta^{11}\text{B} +205.9$).³⁶ For a large number of trigonal boranes an empirical, crudely linear relationship is observed between boron nuclear shielding and the calculated π -electron densities at the boron atoms.

In compounds containing two-coordinate boron, we find rather high ^{11}B nuclear shielding in the iminoboranes, $\text{R}-\text{B}\equiv\text{N}-\text{R}'$ ($\delta^{11}\text{B} \approx 0$ to $+20$) and deshielded ^{11}B nuclides if

Table 7 Nuclear Shielding of Alkalide Anions

	$[\text{Na}]^-$	$[\text{K}]^-$	$[\text{Rb}]^-$	$[\text{Cs}]^-$
δM	–62	–105	–185	–280

	$\delta^{11}\text{B}$	$\delta^{11}\text{B}$	$\delta^{11}\text{B}$	$\delta^{11}\text{B}$	$\delta^{11}\text{B}$	$\delta^{11}\text{B}$	$\delta^{11}\text{B}$
BF_3	10.0	BCl_3	46.5	B(OMe)_3	18.3	B(SMe)_3	61.0
MeBF_2	28.2	MeBCl_2	62.3	MeB(OMe)_2	29.5	MeB(SMe)_2	66.3
Me_2BF	60.1	Me_2BCl	75.5	Me_2BOMe	53.0	Me_2BSMe	74.0
						$\text{B(NMe}_2)_3$	27.3
						$\text{MeB(NMe}_2)_2$	33.5
						Me_2BNMe_2	44.6

the symmetry is reduced, e.g. in $[\text{R-B=NR'R''}]^+$ ($\delta^{11}\text{B} \approx +36$ to $+60$). As for other pairs of isostructural and isoelectronic boron and carbon compounds, this situation is similar to the greatly different $\delta^{13}\text{C}$ values of alkyne derivatives and vinyl cations, if one substitutes the BN by the CC moiety. Many trigonal boranes are used as π ligands in transition metal complexes. The resulting metal–boron interaction, even if it is weak, is in general reflected by the increase in boron nuclear shielding (Table 9).

Table 9 Boron-11 Chemical Shifts of Selected Boranes in π Complexes with Transition Metals. Note the Increased ^{11}B Nuclear Shielding in the Bridging Ligand.

	$\delta^{11}\text{B}$
	+30.0
	+14.0
	+30.0
	+66.0
	+27.3
	+69.0

The ^{11}B resonance signals of borane adducts and borates are also found at low frequencies with respect to boranes, in accord with the increase in CN_B . Clearly, chemical shifts $\delta^{11}\text{B}$ have been very useful in the elucidation of the complex structures of polyboranes, carboranes, and the enormous number of other heteropolyboranes.³⁵

2.3.4 $^{27}\text{Al}^{1,2}$

Chemical shifts $\delta^{27}\text{Al}$ [external reference $\text{Al}^{3+}(\text{aq})$] reflect the CN_Al by ^{27}Al NMR signals at highest frequency for

$\text{CN}_\text{Al} = 3$, at lower frequency for $\text{CN}_\text{Al} = 4$, overlapping with the range for $\text{CN}_\text{Al} = 5$, and at lowest frequencies for $\text{CN}_\text{Al} = 6$. There are few exceptions to this general trend. Since the AlO_4 tetrahedron is an important building block in zeolites, solid state ^{27}Al chemical shifts serve, together with ^{29}Si chemical shifts,¹² for monitoring changes in the structure of zeolites.³⁷ Since MAS cannot remove the anisotropic or line broadening part of the second-order quadrupolar interaction, double rotation NMR has been developed to improve high-resolution solid state NMR spectra of nuclides with half-integer spin such as ^{27}Al ($I = \frac{5}{2}$).

2.3.5 $^{14}\text{N}^{1,2}$

Chemical shift values $\delta^{14}\text{N}$ are identical to those of $\delta^{15}\text{N}$. As a consequence of the high natural abundance of ^{14}N (99.63%), the solution state $\delta^{14}\text{N}$ values are much more readily determined than $\delta^{15}\text{N}$ values. However, owing to efficient quadrupolar relaxation, the ^{14}N NMR signals may be rather broad and, in the case of different ^{14}N NMR signals, the resolution may be insufficient for accurate determination of $\delta^{14}\text{N}$ data.

2.3.6 ^{17}O , $^{33}\text{S}^{1,2,27}$

In spite of its low natural abundance (0.037%) numerous applications of $\delta^{17}\text{O}$ values [external reference H_2O or neat acetone at 301 K ($\delta^{17}\text{O} = +569$, with the absolute frequency $\nu^{17}\text{O} = 13.564\,269\text{ MHz}$)] are reported. In solution, most classes of inorganic oxygen compounds have been studied and a range of $\delta^{17}\text{O} \approx 1650$ has been found, with ^{17}O resonance signals for two-coordinate oxygen in gaseous H_2O ($\delta^{17}\text{O} -36.1$) or Me_2O ($\delta^{17}\text{O} -53$) at low frequency and for $[\text{MnO}_4]^-$ ($\delta^{17}\text{O} = +1230$) or for the terminal and central oxygen atoms in ozone [$\delta^{17}\text{O} = +1032$ (terminal) and $+1598$ (central)] at very high frequencies. The solution structure of the transition metal carbonyl cluster is revealed by the different $\delta^{17}\text{O}$ values of terminal ($\delta^{17}\text{O} \approx +350$ to $+440$) and bridging ($\delta^{17}\text{O} \approx +500$) carbonyl groups. Another field of application of $\delta^{17}\text{O}$ values concerns polyoxometalates, where the ^{17}O nuclear shielding in general increases with the number of metal atoms in the neighborhood. Thus, a terminal oxygen atom is characterized by low shielding with $\delta^{17}\text{O}$ values in the range $\approx +800$ to $\approx +1250$, depending on the metal, although the ^{17}O NMR signals are mostly at higher frequencies compared with those of tetrahedral $[\text{MO}_4]^{n-}$ ($n = 0-3$) (Table 10).

The comparison with $\delta^{17}\text{O}$ values of corresponding tetrahedral main group oxo anions (Table 11) indicates that the electronic structures of the transition metals have a major influence on ^{17}O nuclear shielding.

Solid state ^{17}O MAS NMR spectra of ^{17}O -enriched materials are readily measured, in particular if the oxygen atoms occupy sites of cubic or close-to-cubic symmetry.

Table 10 Oxygen-17 Chemical Shifts in Tetrahedral Oxometalate Anions

	RuO ₄	OsO ₄	[MnO ₄] [−]	[TcO ₄] [−]	[ReO ₄] [−]	[CrO ₄] ^{2−}	[MoO ₄] ^{2−}	[WO ₄] ^{2−}	[VO ₄] ^{3−}
δ ¹⁷ O	+1106	+796	+1230	+749	+569	+835	+530	+420	+568

Table 11 Oxygen-17 Chemical Shifts of Oxo Anions of Main Group Elements

	[ClO ₄] [−]	[SO ₄] ^{2−}	[SeO ₄] ^{2−}	[PO ₄] ^{3−}
δ ¹⁷ O	+290	+167	+204	+113

In alkaline earth metal oxides the δ¹⁷O values range from +22 (BeO) to +640 (BaO), following the changes in cation electronegativity and in the cation radius.

Values of δ³³S [external reference Cs₂SO₄(aq) 2 M with the absolute frequency Ξ³³S = 7.670 123 MHz] have found only limited application as a result of rather broad lines in most cases [exceptions are SF₆, SO₄^{2−}, metal thiocarbonyl complexes and thiooxo metal anions such as MoS_{4−n}O_n^{2−} or WS_{4−n}O_n^{2−} (n = 0–3)] owing to the efficient quadrupolar relaxation. A range of ≈ 1000 ppm has been found with COS (δ³³S = −594) and alkali metal sulfides at lowest frequency and SO₂ (δ³³S = +375) at highest frequency. In general, the δ³³S values follow the trend set by δ¹⁷O values. Hence, changes of solid state δ³³S values of alkaline earth metal sulfides are similar to those of the corresponding δ¹⁷O values.

2.3.7 Some Transition Metal Quadrupolar Nuclides (⁵¹V, ⁵⁹Co, ⁹⁵Mo)^{1,2,28}

Vanadium-51 NMR has been extensively used for all soluble vanadium compounds. Owing to the high NMR sensitivity of the ⁵¹V nucleus, very dilute reaction solutions can be studied. There are large and characteristic ranges of δ⁵¹V values (external reference neat VOCl₃) for various types of vanadium compounds {whole range of δ⁵¹V ≈ −2000, [Ph₃SnV(η⁵-C₅H₅)(CO)₃][−] δ⁵¹V = −2052 to ≈ +4000 (solid Cu₃VTe₄ δ⁵¹V = +3950)}. Important applications concern polyvanadates and heteropolyvanadates and all areas of organometallic vanadium chemistry.

Cobalt-59 NMR signals have provided very early (back to 1951) examples of the chemical shift of metal nuclides. Values of δ⁵⁹Co (external reference K₃[Co(CN)₆] in D₂O 0.1 M with the absolute frequency Ξ⁵⁹Co = 23.727 118 MHz) cover a large range between δ⁵⁹Co ≈ +14 000 to ≈ −4000.^{1,2,28,39} Although it is always pointed out that a crude relationship between the formal oxidation state of cobalt and δ⁵⁹Co exists [increase in ⁵⁹Co nuclear shielding with decrease in the formal oxidation number from Co(III) to Co(−I)], it is important to remember that δ⁵⁹Co values for Co(III) complexes are found in the range between δ⁵⁹Co ≈ +14 000 and 0. In the case of octahedral Co(III) complexes, we find instructive examples of linear correlations between electronic transition wavelengths (as a measure of the average excitation energy, ΔE) and ⁵⁹Co nuclear shielding: a decrease in ΔE causes a decrease in ⁵⁹Co nuclear shielding.⁴⁰

Values of δ⁹⁵Mo [external reference Na₂MoO₄(aq) at pH 11] cover a range of ≈ 6000 ppm with greatest deshielding in compounds with MoMo multiple bonds of the type R₄Mo=MoR₄ (e.g. R = ^tBuC(O)O with δ⁹⁵Mo = +3667) or R₃Mo≡MoR₃ (e.g. R = CH₂SiMe₃ with δ⁹⁵Mo = +3624),

and with high ⁹⁵Mo nuclear shielding in Mo(CO)₆ (δ⁹⁵Mo = −1856), Na[(η⁵-C₅H₅)Mo(CO)₃] (δ⁹⁵Mo = −2123), or [Mo(η⁵-C₅H₅)₂H₃]Cl (δ⁹⁵Mo = −2953).⁴¹ In spite of fairly broad lines, the ⁹⁵Mo shift differences are sufficiently large to distinguish between diastereomers with molybdenum as the chiral center. Molybdenum-95 chemical shift data of polyoxomolybdates and heteropolyoxomolybdates are useful for structural characterization in solution and in the solid state.

3 APPLICATION OF INDIRECT NUCLEAR SPIN–SPIN COUPLING CONSTANTS ^NJ(A,X)

3.1 One-Bond Coupling Constants ¹J(A,X)

All reduced coupling constants ¹K(X,¹H) have a positive sign. Scalar spin–spin coupling across one bond between ¹H and other nuclides (including ¹H) has been extensively studied. Thus, ¹J(¹H,¹H) [measured as ¹J(²H,¹H) in partially deuterated compounds, converted to ¹J(¹H,¹H) values by multiplication with γ¹H/γ²H = 6.514] in η²-H₂ transition metal complexes [¹J(¹H,¹H) ≈ 144 to ≈ 208 Hz]^{42,43} is considerably smaller (Table 12) than in free H₂ [¹J(¹H,¹H) = 278 Hz], indicating the weakening of the strong H–H bond as a result of interaction with the metal. In the absence of a lone pair of electrons at atom X, the magnitude of ¹J(X,¹H) reflects in a qualitative way the so-called ‘s character’ of the X–H hybrid bond orbital and changes in ¹J(X,¹H) fit the model of rehybridization at atom X. Coupling constants ¹J(¹¹B,¹H) in diborane, B₂H₆, demonstrate the dependence of ¹J(¹¹B,¹H) on the s electron density available for the terminal B–H bond [¹J(¹¹B,¹H_t) = 133.5 Hz] and in the two-electron BHB three-center bond [¹J(¹¹B,¹H_b) = 46.3 Hz]. In the case of a closed s shell configuration at atom X (e.g. X = ³¹P in phosphines PH₃, RPH₂ or R₂PH, or ⁷⁷Se in H₂Se, RSeH), changes in the magnitude of ¹J(X,¹H) are much less predictable.

There are numerous applications of ¹J(A,X) values for any suitable combination of A and X (A,X ≠ ¹H). The reduced coupling constants ¹K(A,X) can be of either sign, and there are numerically very small or very large values. So far the largest coupling constant has been measured in the cationic mercury species [Hg–Hg–Hg]⁺ with ¹J(¹⁹⁹Hg,¹⁹⁹Hg) ≈ 139 700 Hz.⁴⁴ If A and X are spin-½ nuclides ¹J(A,X) data are readily obtained from either the A or the X NMR spectra. If one or both nuclides, A or X, are quadrupolar nuclides, the quadrupolar relaxation rate determines whether the measurement of ¹J(A,X) is straightforward (see Section 4). In general, similar to ¹J(X,¹H), the magnitude of ¹J(A,X) can be related to the nature of bonding between these two nuclides, and it provides information on the influence of other substituents at A or X or of the whole molecular structure on the bonding situation. The structural elucidation of polyphosphane and polyborane derivatives by using two-dimensional (2D) homonuclear ³¹P/³¹P and ¹¹B/¹¹B COSY experiments (Figure 6) respectively, serve as examples. Both

Table 12 Transition Metal Complexes with $\eta^2\text{-H}_2$ and Hydride Ligands

$\{\text{MH}(\eta^2\text{-H}_2)[\text{PhP}(\text{OEt})_2]_4\}^+$	$^1J(^1\text{H}, ^1\text{H})$ (Hz)	$T_1(^1\text{H}: \eta^2\text{-H}_2\text{-M})$ (10^{-3}s)	H-M (10^{-3}s)
M = Fe	—	4	65
Ru	208.5	5	90
Os	—	8	44

**Figure 6** Contour plot of the two-dimensional $^{11}\text{B}/^{11}\text{B}$ COSY spectrum at 64.2 MHz of decaborane(14), $\text{B}_{10}\text{H}_{14}$, showing off-diagonal peaks for ^{11}B nuclides linked together via BBB three-center bonds

experiments are based on scalar one-bond spin–spin coupling. In the case of ^{31}P ($I = \frac{1}{2}$), the splittings due to $^1J(^{31}\text{P}, ^{31}\text{P})$ are resolved in the one-dimensional (1D) spectra which, however, may be complex and difficult to analyze with respect to the connectivity of the molecular backbone consisting of many phosphorus atoms. Owing to quadrupolar relaxation of the ^{11}B nuclides ($I = \frac{3}{2}$) most couplings $^1J(^{11}\text{B}, ^{11}\text{B})$ are not well resolved in 1D ^{11}B NMR spectra. Nevertheless, the cross peaks observed in the 2D $^{11}\text{B}/^{11}\text{B}$ COSY experiments are indicative of the connectivity of those boron atoms engaged in BBB three-center bonds, whereas cross peaks for ^{11}B nuclides forming BHB three-center bonds are rather weak and, in most cases, cannot be detected.

The determination of the composition of fluxional cluster compounds in solution can be achieved if coupling is observed (i.e. exchange processes occur intramolecularly). Thus, in Zintl anions of the type $[\text{Sn}_9\text{-}_n\text{Pb}_n]^{4-}$ ($n = 0\text{--}9$) the nature of the anion and its composition follows conclusively from the

relative intensities of ^{117}Sn (Figure 7) or ^{207}Pb satellites [due to $J(^{119}\text{Sn}, ^{117}\text{Sn})$ or $J(^{207}\text{Pb}, ^{117}/^{119}\text{Sn})$] in ^{119}Sn or ^{207}Pb NMR spectra.⁴⁵

3.2 Two-Bond (Geminal) Coupling Constants $^2J(\text{A}, \text{X})$

In many organyl derivatives of various elements X, e.g. X = Si, Sn, Pb, P, Se, Te, or Hg, the coupling constants $^2J(\text{X}, ^1\text{H})$ are routinely measured. Such couplings help to improve the NMR sensitivity of spin- $\frac{1}{2}$ X nuclei by using polarization transfer experiments [INEPT or DEPT, based on coupling constants $^2J(\text{X}, ^1\text{H})$] for direct or inverse detection of the X resonances.

In transition metal chemistry, *cis* and *trans* arrangements of ligands in complexes with square planar, trigonal bipyramidal or octahedral geometry provide a wide field of application of $^2J(\text{A}, \text{X})$ values. Although the greatest number of examples involves A and/or X = ^1H and ^{31}P , there are also important examples for A and/or X = ^{13}C , ^{19}F , $^{119}/^{117}\text{Sn}$, ^{199}Hg ,

**Figure 7** Tin-119 NMR spectrum at 74.6 MHz of the highly fluxional Zintl anion $[\text{Sn}_9]^{4-}$ in ethylenediamine. The parent signal due to $[\text{Sn}_8^{119}\text{Sn}]^{4-}$ is cut off and the satellites are due to the species $[\text{Sn}_7^{119}\text{Sn}^{117}\text{Sn}]^{4-}$ and $[\text{Sn}_6^{119}\text{Sn}^{117}\text{Sn}_2]^{4-}$ (the outer lines of the corresponding triplet are marked by asterisks)

or ^{207}Pb . In general, it is observed that the *cis* coupling pathway leads to fairly small $^2K(\text{A},\text{X})$ values which can be of either sign, whereas the *trans* position of A and X gives much larger couplings, usually with $^2K(\text{A},\text{X}) > 0$. Geminal coupling constants in polytungstates and in heteropolytungstates, in particular if one of the heterotoms is phosphorus, are important for structural assignment in solution. The values $^2J(^{183}\text{W}, ^{183}\text{W})$ across the oxygen atom indicate the nature of W–O–W bridging⁴⁶ and also reflect distortions of WO_6 octahedral units.⁴⁷ Furthermore, it allows us to perform 2D INADEQUATE experiments that enable us to trace the connectivity of tungsten atoms.⁴⁸ The coupling constants $^2J(^{183}\text{W}, ^{31}\text{P})$ across the oxygen atom reveal the environment of the PO_4 tetrahedron in the framework.

3.3 Three-Bond (Vicinal) Coupling Constants $^3J(\text{A},\text{X})$

As described for $^2J(\text{X},\text{H})$, coupling constants $^3J(\text{X},\text{H})$ are measured routinely and serve for various polarization transfer experiments in the measurement of X NMR spectra. Most other applications of vicinal coupling constants deal with the geometric relationship between the nuclides as has been found empirically for $^3J(\text{H},\text{H})$ and as expressed in the Karplus equation⁴⁹

$$^3K = C \cos 2\Phi + B \cos \Phi + A$$

in which Φ is the dihedral angle and A, B, and C are constants depending on the coupled nuclides, on the electronegativity of substituents, and on the nature of the intervening atoms.

4 APPLICATION OF NUCLEAR SPIN RELAXATION PARAMETERS

4.1 Structural Information

Although dipolar interactions between magnetically active nuclides in liquids are averaged, these interactions can still be responsible for relaxation ($T_1^{\text{DD}}, T_2^{\text{DD}}$, depending on r_{AX}^6), which can be proved by 1D or 2D NOE measurements (NOESY, etc.). These are of prime importance in biochemistry applications, in particular for homonuclear NOE between protons, but it is certainly also a useful approach in inorganic chemistry. In some cases decisive structural information can already be gained by measuring T_1 values as shown for complexes containing the $\eta^2\text{-H}_2\text{-M}$ group and the corresponding hydrides with M–H bonds. The persistent H–H bond in the former is identified by much shorter T_1^{H} values compared with the $\eta^1\text{-hydrides}$ ⁵⁰ (Table 12).

With few exceptions (e.g. ^2H , ^6Li , ^7Li , ^9Be) the nuclear spin relaxation of quadrupolar nuclides ($I > \frac{1}{2}$) in liquids is dominated by electric quadrupole interactions. Consequently, large quadrupolar coupling constants reflecting an asymmetric distribution of charge around the nucleus, are related to broad resonance signals or short relaxation times T_Q [$W_{1/2} = (\pi T_Q)^{-1}$]. This can be used for studying the coordination sphere of cations (e.g. Na^+ , Cs^+ , Mg^{2+} , etc.) or anions (e.g. Cl^- , Br^- , ClO_4^- , SO_4^{2-} , etc.) in solution. Similarly, different

linewidths as a result of quadrupolar relaxation support the structural assignment in mixtures of octahedral complexes [e.g. of Co(III) or of Al(III)]. If the local symmetry at the quadrupolar nucleus does not change, but the molecular size increases, this will cause an increase in the linewidth of the NMR signal. Hence equilibria involving intermolecular association are readily shown.

If a paramagnetic material is added to a diamagnetic sample, the relaxation processes are significantly perturbed owing to the very large magnetogyric ratio of the electron. This has been used to shorten T_1 values (relaxation agent) or to simplify complex ^1H NMR spectra (shift agent). In the latter case, it is also possible to obtain structural information if the shift in the ^1H NMR spectra results from interactions between a polar group in the diamagnetic species with the paramagnetic metal center (usually a lanthanoid metal).

4.2 Chemical Exchange

There are many labile bonding situations in inorganic chemistry, leading eventually to chemical exchange, either intra- or intermolecularly. These processes are reflected by temperature-dependent changes of the linewidth $W_{1/2}$ of the relevant NMR signals and/or by the appearance of a typical splitting pattern due to spin–spin coupling [e.g. $[\text{B}_3\text{H}_8]^-$ (Figure 8), ClF_3 , SF_4 , or pseudorotation in fluorophosphoranes] if the rate of the exchange processes fits the NMR timescale defined by chemical shifts and coupling constants (see Figure 8). However, this timescale can be readily expanded for monitoring very fast or rather slow processes by making use of nuclear spin relaxation behavior.

Slow processes may be simply revealed by time-dependent signal intensities, a very basic approach to the study of kinetics. If the rate of chemical exchange corresponds to the spin–lattice relaxation time T_1 of the nuclides involved, various 1D and 2D techniques (based on magnetization- and spin-saturation transfer) are available to monitor such exchange processes. The nature of the Wilkinson catalyst in solution in the presence of an excess of triphenylphosphine (Figure 9) is an instructive example.⁵¹

Fast exchange processes can be characterized by determining the difference between spin–spin and spin–lattice relaxation times. The exchange contribution to T_2 , $(T_{2,\text{ex}})^{-1}$ is dependent on B_0^2 , which means that high-field NMR spectrometers open up the access to fast exchange rate constants (up to 10^7 to 10^8 s^{-1}).

4.3 Motion in Liquids and Solids

Most major relaxation mechanisms both in solution and in the solid state arise from some sort of motion. There are too

Figure 8 Fast intramolecular exchange between, and bridging hydrogen atoms in, the anion $[\text{B}_3\text{H}_8]^-$, leading to an averaged coupling $J(^{11}\text{B}, ^1\text{H}) = 33 \text{ Hz}$ (the ^{11}B NMR spectrum at 64.2 MHz shows seven of the expected nine lines with the correct ratio)

Figure 9 Spin saturation transfer experiment (based on DANTE) showing that intramolecular exchange between sites A and B is much faster (see the experiment with 0.3 s delay) than intermolecular exchange with free Ph_3P . The splitting of the signals A and B arises from $^1J(^{103}\text{Rh}, ^{31}\text{P})$ and $^2J(^{31}\text{P}, ^{31}\text{P})$. The ^{31}P spectra were recorded at 81.0 MHz

many different roots and applications, which are clearly not related just to inorganic chemistry, in order to discuss this topic in detail. The rotational correlation times in solution can be determined, e.g., by NOE measurements of spin- $\frac{1}{2}$ nuclides, by measurement of T_Q of quadrupolar nuclides (if the quadrupolar coupling constant is known), or by using information on the anisotropy of nuclear shielding. MAS in the solid state has opened the way to study the dynamic behavior of solids more accurately and more conveniently as shown in the case of the mobility of π bonded aromatic ligands or carbonyl groups in organometallic compounds.⁵²

1 INTRODUCTION

The reactions and physical properties of transition metal complexes are determined, naturally enough, by the nature of the metal. Historically, for metal complexes, classical methods of investigation relied heavily on ultraviolet/visible and infrared methods; however, these were often not capable of providing enough detail, especially for the relatively pale or colorless complexes of the third transition series. It was recognized early on¹ that direct observation of the NMR signal from a transition metal center would be advantageous since the metal chemical shift was determined to be very sensitive to its chemical environment. Nevertheless, progress in measuring metal NMR spectra was slow since most of the $I = \frac{1}{2}$ metal nuclei possess small magnetic moments and/or are not found in high natural abundance. Table 1 shows relative sensitivities and natural abundances for the transition metal isotopes, ⁵⁷Fe, ⁸⁹Y, ¹⁰³Rh, ^{107,109}Ag, ^{111,113}Cd, ¹⁸³W, ¹⁸⁷Os, ¹⁹⁵Pt, and ¹⁹⁹Hg, the subjects of this article. Not all of these are low sensitivity nuclei, e.g. ¹¹³Cd, ¹⁹⁵Pt, and ¹⁹⁹Hg are comparable to, or even easier to measure than, ¹³C; nevertheless, it is reasonable to consider these together with the other, less sensitive nuclei. Where two isotopes with $I = \frac{1}{2}$ are present, e.g. silver and cadmium, it is usually the product of the relative sensitivity and the natural abundance which determines the selection, so that measurements on the isotopes ¹⁰⁹Ag and ¹¹³Cd are usually preferred. There are a number of useful review articles which discuss aspects of the NMR spectroscopy for these nuclei in detail.²

2 METHODOLOGY

The earliest continuous wave,³ and later INDOR, spectra were often obtained from relatively concentrated solutions but were nevertheless often unsatisfactory from a signal-to-noise viewpoint. In the early 1970s the introduction of pulsed NMR methods together with accumulation and ¹H decoupling

procedures combined to improve matters by several orders of magnitude.⁴

These pulsed NMR experiments were carried out using comparatively low field instruments, so that the relatively long spin–lattice relaxation times (T_1) for some metal nuclei proved a problem. It was normal to overhear colleagues discussing the difficulties associated with obtaining a particular ⁵⁷Fe or ¹⁰³Rh signal, and the source of the problem was not always certain. We know today that T_1 relaxation processes for these relatively insensitive metal spins are often dominated by the shielding anisotropy relaxation mechanism. Indeed, it is no longer uncommon to find published T_1 values on the order of milliseconds for measurements made at 9.39 or 11.74 T.

In the 1980s the increasing commercial availability of spectrometers with both pulse programmers and higher magnetic fields ushered in a new era of interest in measuring spin $I = \frac{1}{2}$ nuclei. Although the increased signal-to-noise ratio was, in some cases, offset by an increase in the metal resonance linewidth, i.e. shorter T_2 values,^{2a,b} it was much easier to implement new advantageous pulse sequences. The first major step forward came with the use of polarization transfer methods such as INEPT,⁵ in that the metal signal can be enhanced by a factor of γ_H/γ_M , where γ_M is the magnetogyric ratio of the metal nucleus M (and is directly proportional to its magnetic moment). In the INEPT procedure, spin (I) polarization (which usually means ¹H, but can be ¹⁹F or ³¹P) is transferred to the spin = $\frac{1}{2}$ metal (S) via pulse sequence (a) shown below:

If decoupling is required, the scheme should be extended as shown in pulse sequence (b):

Examples of this methodology are shown in Figures 1 and 2. Mann^{2b} gives the optimum delay, τ_1 , for differing numbers of I spins coupled to the metal center.

The major limitation with INEPT arises from the necessity of having a spin–spin coupling between the metal and a suitable proton in the complex. Unfortunately, this condition is frequently either not fulfilled [e.g. Fe(CO)₅, RhCl₃, Cd(ClO₄)₂, K₂PtCl₆, etc.] or one is not aware that a suitable interaction is present. An interesting example of this latter variant will be shown in connection with ¹⁸³W, in Figure 3. INEPT spectra can appear somewhat strange in that the multiplets reveal both positive and negative phases (typically a +1:–1 doublet or a +1:0:–1 triplet, and occasionally a +1:+1:–1:–1 quartet).

The most sensitive, and now routinely used, approach to obtaining spin $I = \frac{1}{2}$ metal NMR signals involves double polarization transfer⁶ ($I \rightarrow S \rightarrow I$) and uses one of the following two-dimensional sequences, with optional pulses shown in braces:

2 INORGANIC NUCLEI: LOW SENSITIVITY TRANSITION METALS

Table 1 Transition Metals with $I = \frac{1}{2}$

with the I spins again assumed to be a high receptivity nucleus, most often ^1H , but occasionally ^{31}P . The time τ is set to $\leq 1/2 J(S, I)$, and the time t_1 represents the time variable for the second dimension. These sequences provide a theoretical

Heteronuclear single quantum coherence (HSQC)

Figure 1 $^{103}\text{Rh}\{^1\text{H}\}$ INEPT spectrum, recorded with pulse sequence (a), of the complex shown, $\text{L} = \text{PPh}_3$. The fine structure arises from the small splitting due to the hydride proton (1), the two PPh_3 ^{31}P spins (2), and one $\text{P}(\text{OMe})_3$ ^{31}P spin (3). (Reproduced by permission of Wiley from Blumer et al.³⁷)

Figure 2 Conventional and $^{109}\text{Ag}\{^{31}\text{P}\}$ INEPT spectra, recorded with pulse sequence (a), of 0.6 M $[\text{Ag}(\text{dppe})_2]\text{NO}_3$, dppe = bis(diphenylphosphino)ethane, at 300 K. (a) Normal acquisition (12 111 pulses), 2 s delay 50° pulse; (b) $^{109}\text{Ag}\{^{31}\text{P}\}$ INEPT, 2048 repetitions, $\tau = 93$ ms. enhancement of $(\gamma_I/\gamma_S)^{5/2}$. For nuclei such as ^{57}Fe and ^{103}Rh this means factors of 5328 and 5689, respectively, and ‘only’ 2831 for ^{183}W . The metal data are detected using the proton signals, and the spectra are usually presented as contour plots, as shown in Figures 3–5. For a complex of molecular weight 500–1000, one can obtain good quality ^{183}W data from about 25 mg in approximately 30 minutes.⁷

Once again, the success of this technique depends upon the presence of a spin–spin interaction between the metal and a suitable I spin (usually a proton in a ligand). For the pulse sequences (a) through (d) it is common to introduce a relaxation delay before repeating the sequences. It is interesting to note that, in Figure 3, there are cross peaks which arise due to spin–spin interactions from the ^{183}W to both the *ortho* and *para* protons of the aryl moiety.⁷ These previously unknown coupling constants are < 1 Hz and could only be recognized using this type of inverse detection. One finds, increasingly, that inverse methodology is the best way of determining small, not readily measured spin–spin interactions with the transition metal center.

Since the ease with which one can readily detect an $^nJ(\text{M}, \text{H})$ interaction in a one-dimensional experiment is proportional to the size of the magnetic moment of M (small J values are lost in the linewidth when the natural abundance of M is $< 100\%$), there is little known with respect to two- and three-bond coupling constants for ^{57}Fe , ^{103}Rh , ^{109}Ag , ^{183}W , and ^{187}Os , but quite a lot for ^{195}Pt and ^{199}Hg . However, for metal complexes containing phosphorus ligands in which the ^{31}P is directly bound to the metal center, one always has a relatively large $^1J(\text{M}, \text{P})$ value of the order of 10^2 – 10^3 Hz.⁸ For instruments equipped with a suitable probehead, one can obtain inverse two-dimensional ^{57}Fe – ^{31}P and ^{109}Ag – ^{31}P spectra such as shown in Figures 6 and 7. The ratio $(\gamma^{31}\text{P}/\gamma_{\text{M}})$, and thus the polarization transfer, is not so favorable as for ^1H ; nevertheless, theoretical enhancements of 593 and 295 are possible for ^{103}Rh and ^{183}W , respectively.

3 RELAXATION TIMES

In contrast to a nucleus such as ^{13}C , the relaxation of a spin $= \frac{1}{2}$ metal is not generally controlled by the dipole–dipole relaxation mechanism and there is little or no proton induced NOE. However, ^1H NOE to ^{113}Cd has been observed,⁹ and dipole–dipole relaxation has also been found for ^{113}Cd in the protein calbindin D_{9k}.¹⁰ The two most frequently observed T_1 relaxation mechanisms derive from (a) the metal shielding anisotropy (SA),

$$1/T_{1,\text{SA}} = \frac{2}{15} \gamma_{\text{metal}}^2 B_0^2 \Delta\sigma^2 \tau_c \quad (1)$$

where γ is the magnetogyric moment, B_0 is the magnetic field strength, σ represents the shielding anisotropy, and τ a molecular reorientation correlation time, and (b) spin rotation (SR),

$$1/T_{1,\text{SR}} = IkTC^2\tau_{\text{SR}} \quad (2)$$

where I is the moment of inertia, C the spin–rotation coupling constant, and τ_{SR} the correlation time for spin–rotation.

In recent studies^{2a,2b} it has been recognized that the SA relaxation is generally (but not always) the more important of the two, and especially so if the T_1 values are determined using relatively high field magnets. Solid state measurements on spin $= \frac{1}{2}$ metals have shown that the SA can be thousands of parts per million.^{2a,11} Indeed, it is not always possible to rotate the solid sample fast enough to avoid finding useful, but none the less complicated sideband patterns.¹¹ There is no simple rule allowing one to estimate T_1 for the metal in a complex; however, the literature^{2a,2b} shows that most values lie between 10^{-1} and 10^2 seconds. For complexes with large SA values, the T_1 values can be of the order of milliseconds^{12,13} as noted above. Specifically, in the two-coordinate complex $\text{Hg}(\text{CH}_2\text{Ph})_2$,¹³ the T_1 values are 73.7 ms at 5.8 T and 35.6 ms at 9.4 T, whereas for the platinum(0) complex $\text{Pt}(\text{PPr}^i_3)_2$ one finds $T_1 = 25$ ms at 9.4 T and 97 ms at 4.7 T.¹² The last two T_1 values clearly show the dependence of the ^{195}Pt T_1 on B_0^2 . For smaller SA values, i.e. more symmetrical complexes, T_1 can be much longer, e.g. 240 s for ^{89}Y in $\text{Y}(\text{NO}_3)_3$.¹⁴

Figure 3 Sections of the 11.7 T ^{183}W - ^1H HMQC shift correlation for the complex shown. Note that there are cross peaks for both the *ortho* and *para* protons of the imidophenyl group (C_6D_6). (Reproduced by permission of Wiley from Macchioni et al.⁷)

4 CHEMICAL SHIFTS

It is now widely accepted that chemical shifts of heavy nuclei depend upon the paramagnetic contribution to the total screening, σ_p .¹⁵ For a transition metal nucleus this means an expression related to

$$\sigma_p \propto \langle r^{-3} \rangle \sum_j^{\text{occ}} \sum_k^{\text{unocc}} (E_k - E_j)^{-1} S \quad (3)$$

where r is a distance term, E_k and E_j are molecular orbital energies for unoccupied and occupied levels, and S is a sum involving the d orbital coefficients of the atomic orbitals used in making up the molecular orbitals.

As it is frequently not simple to obtain a clear molecular orbital picture for the metal center in low symmetry complexes with several different ligands, the analysis of metal chemical shifts remains, with some few exceptions,¹⁶ on an empirical basis. The range of transition metal chemical shifts is of the order of thousands of parts per million and, for a given nucleus, e.g. ^{57}Fe , ^{103}Rh or ^{195}Pt , frequently in excess of 10 000 ppm. For the nuclei $^{107,109}\text{Ag}$, $^{111,113}\text{Cd}$, and ^{199}Hg , which often have the d^{10} electronic configuration, the range of chemical shifts is somewhat smaller than for those metal centers with less than 10 d electrons. Not surprisingly, the metal chemical

shift is very sensitive to changes in—and close to—the coordination sphere. Solvent effects are routinely tens of parts per million.² Changes in temperature during a measurement result in large enough shifts (often in the range 0.1–0.5 ppm per degree) such that fine structure on the resonance is easily ‘blurred’,^{2b} and isotope effects, e.g. ^{35}Cl vs. ^{37}Cl ,^{2b} ^{16}O vs. ^{18}O ,¹⁷ or ^1H vs. ^2H ,¹⁸ are sufficiently large such that the different chemical shifts from the individual isotopomers are often well resolved (see Figure 5).

The subject of referencing for metal chemical shifts is not clearly settled. There are several schools of thought: (a) referencing to a readily (usually commercially available) compound, (b) referencing to the metal, and (c) referencing to a frequency based on the ^1H frequency of tetramethylsilane at 100 000 000 MHz. Table 1 offers some commonly used references for the spin $I = \frac{1}{2}$ metals under discussion here. Where metal chemical shifts are concerned it is common to find both positive and negative signs with the latter denoting lower frequency than the reference.

Typical examples of the sensitivity of the chemical shift, δ , to the presence of different ligands are given in Figures 8 and 9. In the former, the metal signals were detected using the protons, and there are (a) cross peaks which arise from the coordinated ethylene molecule of the anion and (b) cross peaks arising from the protons of the chiral tridentate ligand

Figure 4 ^{109}Ag - ^1H HMQC of a silver substituted yeast metallothioneine, with an additional 90° pulse applied just after the refocusing interval to transfer magnetization from the NH to the H- α protons. The seven resonances are marked by roman numerals according to their increasing chemical shifts. The blank circles indicate the position of observed cross peaks in a similar experiment acquired with a preparation period of 45 ms ($J = 11.1$ Hz). (Reproduced by permission of the American Chemical Society from S. S. Narula, R. K. Mehra, D. R. Winge, and I. M. Armitage, *J. Am. Chem. Soc.*, 1991, **113**, 9354)

of the formally cationic platinum.¹⁹ Figure 9 shows a one-dimensional solid state ^{113}Cd spectrum in which there are two different metal environments. One cadmium has two PPh_3 ligands coordinated and appears at high frequency as a triplet, whereas the phosphine free CdCl_2 absorption appears at lower frequency.²⁰

There are not many general empirical chemical shift correlations which are valid for all of the spin $I = \frac{1}{2}$ metal centers. The higher metal oxidation states [Fe(II) vs. Fe(0) , Rh(III) vs. Rh(I) , or Pt(IV) vs. Pt(II)] are often found at higher frequency. For the metal centers with <10 d electrons, analogous halogen complexes often show algebraically smaller δ values (lower frequencies) when one moves down the column, i.e. $\text{Cl} > \text{Br} > \text{I}$. This latter trend is demonstrated by the selected examples in Table 2.

In some complexes there may be a correlation of the metal chemical shift with an empirical characteristic of the ligand(s), e.g. hardness or softness; however, these are not general effects for all of the metals,¹⁶ and many exceptions are known [e.g. what is hard and what is soft may change with the oxidation state; or signals from the higher oxidation state platinum(II) can appear at lower frequency² than for some signals arising from platinum(0)]. It is important to remember that σ_p in equation (7) contains no expression related to any of these metal or ligand chemical characteristics. In any given complex either the $\langle r^{-3} \rangle$ or the $(E_k - E_j)^{-1}$ term may prove to be

dominant, so that there is no reason to expect generality for all, or even many, of the metal centers. This point is valid for both spin $I = \frac{1}{2}$ and quadrupolar transition metal chemical shifts. Naturally, the nature of the specific chemistry will affect both the distance and energy parameters.

5 COUPLING CONSTANTS

The theory for spin-spin interactions between a spin $I = \frac{1}{2}$ metal and an appropriate ligand atom follows directly from the description developed by Pople and Santry.²⁴ A modified form of the expression is

$$^1J(\text{M,L}) \propto (\gamma_{\text{M}})(\gamma_{\text{L}})|\psi_{\text{s(M)}}(0)|^2|\psi_{\text{s(L)}}(0)|^2 \times \sum_j^{\text{occ}} \sum_k^{\text{unocc}} (E_k - E_j)^{-1} C(\text{M})_k^{\text{s}} C(\text{L})_k^{\text{s}} C(\text{M})_j^{\text{s}} C(\text{L})_j^{\text{s}} \quad (4)$$

which reveals that the one-bond interaction depends on the metal and ligand atom magnetogyric ratios γ , the s expectation values ψ , the molecular orbital energies, and the s coefficients of the atomic orbitals used in making up the molecular orbitals.

Given that the γ and s expectation values ψ depend markedly on the individual metal and ligand atoms under

Figure 5 (^1H , ^{103}Rh)- $\{^2\text{H}\}$ HMQC correlation spectrum for $\text{RhY}_2(\text{Y}_2)(\text{HB}(3,5\text{-Me}_2\text{pz})_3)$ ($\text{Y} = ^1\text{H}$ or ^2H ; pz = pyrazolyl). The hydride ligands exchange rapidly on the NMR timescale with the hydrogen atoms of the coordinated H_2 molecule, so that four different isotopomers arise. (Reproduced by permission of Wiley from D. Nanz, W. von Philipsborn, U. E. Bucher, and L. M. Venanzi, *Magn. Reson. Chem.*, 1991, **29**, S38)

consideration, it is not surprising that the signs and magnitudes of these spin–spin interactions vary enormously.

For hydride as the ligand, the magnitude of $^1J(\text{M}, ^1\text{H})$ can be as small as a few hertz for $\text{M} = \text{W}$,²⁵ or in excess of 1000 Hz for $\text{M} = \text{Pt}$,^{2a,26} with the largest value, of $^1J(^{195}\text{Pt}, ^1\text{H})$, at about 1606 Hz.²⁷ One-bond $^1J(^{109}\text{Ag}, ^1\text{H})$,²⁸ $^1J(^{103}\text{Rh}, ^1\text{H})$,²⁹ and $^1J(^{187}\text{Os}, ^1\text{H})$ ^{2a} values are much smaller than $^1J(^{195}\text{Pt}, ^1\text{H})$, and frequently are of the order of 10–100 Hz. As the s coefficients C are important, one finds that, for $\text{L} = ^{13}\text{C}$, the hybridization of the carbon affects the magnitude of $^1J(\text{M}, ^{13}\text{C})$ such that sp carbons (with a higher percentage of s character) afford larger values than for analogous complexes with an sp^3 carbon ligand. For the complexes $\text{cis-Pt}(\text{CH}_3)_2(\text{PMe}_2\text{Ph})_2$, $\text{cis-Pt}(\text{C}_6\text{H}_5)_2(\text{PET}_3)_2$, and $\text{Pt}(\text{CN})_4^{2-}$, with sp^3 , sp^2 , and sp coordinated carbons one observes values³⁰ of $^1J(^{195}\text{Pt}, ^{13}\text{C})$ at 594, 817, and 1036 Hz, respectively, reflecting these differing coefficients. The hybridization at carbon is clearly not the only factor involved and this explains why the $^1J(^{195}\text{Pt}, ^{13}\text{C})$ values are not exactly in the ratio 1.0:1.3:2.0.

There is an extensive literature on $^1J(\text{M}, ^{31}\text{P})$ ^{2a} for complexes with directly bound phosphorus ligands.⁸ Since

Figure 6 Inverse two-dimensional ^{57}Fe - ^{31}P spectrum of the complex shown, at 161.2 MHz. The scalar couplings of both ^{31}P and ^{57}Fe with deuterium can be extracted from the contour plot. The asterisks denote the incompletely suppressed lines of the parent signal with magnetically inactive iron. (Reproduced by permission of the American Chemical Society from Benn et al.^{6b})

both the γ and s expectation values, $|\psi_s(0)(\text{L})|^2$, for ^{31}P are relatively large, one finds spin–spin interactions of the order of 10^2 – 10^4 Hz, depending upon the metal and the nature of the phosphorus ligand. $^1J(\text{M}, ^{31}\text{P})$ has become an important analytical tool in the determination of molecular structure of phosphine complexes. The development of cisplatin [$\text{cis-PtCl}_2(\text{NH}_3)_2$] and related cancer drugs has been accompanied by a renewed interest in $^1J(^{195}\text{Pt}, ^{15}\text{N})$.^{26,31,32} This parameter varies between 88 and 821 Hz. For the specific complexes containing the fragment ' $\text{cis-Pt}(\text{NH}_3)_2$ ' the values are often between 200 and 400 Hz. An extensive list of $^1J(^{195}\text{Pt}, ^{15}\text{N})$ coupling constants can be found in the literature.²⁶ Spin–spin interactions between the metals themselves vary between a few hertz, as in the case for two rhodium atoms,³³ up to many thousands of hertz for the metal nuclei with larger γ values.

There are several useful empiricisms involving coupling constants of spin $I = \frac{1}{2}$ metal centers: (a) $^1J(\text{M}, \text{L})$ the magnitude depends on the *trans* influence^{2a,8} of the ligand situated opposite to L, with stronger donors resulting in markedly reduced values, and (b) there can be the usual

Table 2 δ Values for Halogen Complexes of Metals with $<10d$ Electrons

Complex	X				Reference
	F	Cl	Br	I

Figure 7 ^{109}Ag – ^{31}P HSQC spectrum of the bis-isonitrile complex shown. There is only one ^{109}Ag resonance whose splitting in the metal direction represents the sum of the two $^1J(^{109}\text{Ag}, ^{31}\text{P})$ values. The two different ^{31}P signals overlap. (Reproduced by permission of the American Chemical Society from F. Lianza, A. Macchioni, P. S. Pregosin, and H. Rügger, *Inorg. Chem.*, 1994, **33**, 4999)

Karplus type relationship associated with $^3J(\text{M}, ^1\text{H})$ or $^3J(\text{M}, ^{13}\text{C})$, although this is not always as well developed as for $^3J(^1\text{H}, ^1\text{H})$.

6 APPLICATIONS

There are certainly many instances in which the metal chemical shift was recorded primarily to learn where it could be found. This was often the case in the early years

Figure 8 ^{195}Pt – ^1H spectrum of the complex shown. There is a complex cation (relatively weak cross peaks from both the *meta* pyridine proton and the heterocyclic ring methine proton) and a complex anion (relatively strong cross peak from the coordinated ethylene) and the metal direction reveals the considerable difference in their chemical shifts. It is not obvious from the ^1H spectrum that two different metal centers are present. (P. S. Pregosin, K. Püntener, and H. Rügger, unpublished results)

Figure 9 CP–MAS $^{113}\text{Cd}\{^1\text{H}\}$ NMR spectrum at 33.30 MHz of the solid isolated from the reaction of PPh_3 with CdCl_2 in a 1:1 ratio. The singlet at 200 ppm is due to CdCl_2 , and the triplet at 590 ppm is due to $\text{CdCl}_2(\text{PPh}_3)_2$. (Reproduced by permission of Wiley from Kessler et al.²⁰)

since—given the sensitivity of δ —it was not always certain that the resonance could be immediately located. Indeed, one still finds worthwhile studies involving compilations of chemical shifts, and there is no doubt that this body of empirical data is appreciated by many chemists. The Appendix provides a few examples of how and why these metal nuclei are currently being measured.

The more chemical reasons for measuring a spin $I = \frac{1}{2}$ metal spectrum are usually associated with:

1. the desire to prove the presence and specific number of one or more coordinated ligands;
2. an interest in learning about the ground state physical properties of a particular ligand, e.g. the *trans* influence;
3. the need for a unique probe with which to follow the kinetics of a reaction;¹⁶
4. the intention to correlate one or more NMR parameters with physical data from other methods,³⁴ e.g. ultraviolet, visible or infrared energies, or perhaps reduction–oxidation data; and
5. an inherent interest in the NMR properties for their own sake, e.g. signs of coupling constants in which transition metals are involved.^{35,36}

The first of these is, statistically, the most abundant application. A particular chemical shift may be indicative of the presence of some ligand and/or coordination number.³⁷ The observation of a signal at very high or low frequency may be more consistent with one oxidation state than another. Often one finds that the multiplicity of the metal signal^{37–41} or the relative intensities of weak satellite lines⁴¹ provide keys to a particular structural puzzle. Does the metal spectrum appear as a doublet or a triplet? How many ²⁹Si or ¹¹⁹Sn or ¹⁹⁵Pt spins (all of which are <100% abundant) are within the coordination sphere? These decisions cannot always be made using ¹H, ¹³C, or some other NMR form, and this is especially true for homogeneous catalysts based on metal complexes since the organic reagents are present in a 100-fold or more excess.

The magnitudes of ¹J(M, L) or ⁿJ(M, L) can be employed as structural tools in that one knows that these parameters can be theoretically and empirically related to the geometry of square-planar or octahedral complexes.^{8,30} This has led to many useful NMR empiricisms (the largest database involves ¹⁹⁵Pt) relating the ability of a coordinated ligand to weaken the ligand *trans* to it in the equilibrium state.^{26,42} There are literally dozens of interesting coupling constants; however, two mercury examples stand out: for the Hg₃²⁺ ion,⁴³ ¹J(¹⁹⁹Hg, ¹⁹⁹Hg) = 139 700 Hz and in IrCl(SnCl₃)(HgCl)(CO)(PPh₃)₂, ²J(¹⁹⁹Hg, ¹¹⁹Sn) = 41 479 Hz.²³ The former is unique in that it represents the largest reported spin–spin coupling, and there is only the one example. The two-bond interaction is also amongst the largest of its kind, but is not unique in that several derivatives have been prepared and a 39 294–42 688 Hz range observed. Despite the existing richness, there is still much more to come from both spin $I = \frac{1}{2}$ and spin $I > \frac{1}{2}$ transition metal NMR.
